SANITARY ENGINEERING

Sanitary Engineering. By Baldwin Latham. Second Edition. (E. and F. N. Spon, 1878.)

IN the introduction to this book great stress is laid on the necessity for sanitary measures being thoroughly carried out in all towns and dwellings; one might suppose that this was fully admitted on all sides, but we have no doubt that every medical officer of health throughout the country could easily give numberless instances of the greatest possible neglect and callousness on the subject. While all admit the necessity of efficient sanitary works and are generally quite ready to attribute to defective arrangements illness occurring in a neighbour's house or another town, each individual seems to ignore the possibility of a terrible punishment falling on him for his own neglect. He should recollect that the punishment which must sooner or later overtake him cannot be moderated by the clemency of a chairman of Quarter Sessions or the gentler feelings of a jury, but is ruthlessly administered by the inexorable laws of nature.

Mr. Baldwin Latham doubtless finding it almost useless to preach to people on the necessity of taking care of their own and their neighbours' health very wisely tries an appeal to them through their pockets, and shows the amount of actual pecuniary saving from improvements in the sanitary condition of a community. The town of Croydon is taken as an instance; in this case the average mortality from 1848-55 inclusive was 24·03 per thousand, while that for the twenty years since 1855, when the sanitary works were nearly completed, has averaged 19·56, showing a saving of 4·47 per thousand. But this is not all that is to be looked for; there is evidence that at times the mortality of Croydon proper is considerably increased by an impure water supply, and from the lower mortality of Norwood it appears that a still further improvement could be obtained by the adoption of suitable measures. Multiplying the average saving in the rate of mortality by the population and by the assumed value of labour per head taken at 19*l.* 10*s.* per annum after a deduction of nearly one-half for persons of an unsuitable age for work, the author obtains 413,395*l.* as the value of the saving from the lessened number of deaths in ten years on an average population of 43,912. The saving in cases of sickness not resulting in death is taken at 1*l.* per case on twenty-five times the number of deaths, that being the estimated ratio of cases of illness to deaths; this gives 98,150*l.* as the result, and to this is added the cost of funerals saved, 3,926 at 5*l.* each equal to 19,630*l.*, or a total saving of 531,375*l.* It would appear to us more correct to leave out this last item, as the expense though saved for the present must be regarded as a deferred charge and must be incurred sooner or later. The works having cost in this case 267,665*l.* there remains as a dividend for the twenty years an amount in the aggregate equal to nearly twice the capital. This in the days of discarded gas and failing banks ought, unaided by the arguments of zymotic disease, to persuade the ratepayer to seek an investment in sanitary progress.

A great number of very useful tables are embodied in the text; those of the velocity and flow in pipes and sewers from p. 91 to 153 will be found of great service to the sanitary engineer, being calculated over a much greater range than in other books on the subject, and having been extended in the present edition. We should suggest with reference to tables 29, 30, 31 that a very useful addition to make in a future edition would be a table of areas and hydraulic mean depths with other fractional depths of flow besides one-third and one-half full, and that the use of the velocity and discharge tables would be facilitated by giving the corresponding fall in feet per mile side by side with the given rate of inclination expressed in a numerical ratio.

A chapter is devoted to the question of the admission of rainfall into sewers; the reasons for its exclusion as far as practicable are stated to be (1) to increase the manurial value of the sewage; (2) to obviate the inconvenience attending the purification of a large and uncertain volume of sewage in times of rainfall; and (3) to give to the streams of the country the natural volume of water due to the rainfall within their collecting area, and the adoption of this course receives but partial

recommendation. We believe the author has omitted by far the most important reason, viz., the deposit of heavy road detritus caused by the admission of storm waters, which retards the free flow of the sewage and retains a mass of decomposable matter in the sewers quite sufficient to account for the abominable effluvium emitted by the gullies and ventilators of the London system. A reason advanced for the admission of surface water into sewers given by the author, and to which much weight is attached, is the fact that it was found by the analyses of Prof. Way that the washings from the streets of London resulting from rainfall were equal in impurity to average sewage. If the surface of our streets is permitted to become so filthy that, even when diluted with rain-water, the product is only suited for admission into the sewer, it would surely be better to turn more attention to the collection and carting away of the filth rather than to get it washed away out of sight where its presence will not be remarked until the next dry weather renders it painfully apparent. It is somewhat to be regretted that the author has not devoted a small amount of space to a subject having so important a bearing on the sanitary condition of a town and the successful operation of a system of sewerage as the scavenging of streets, especially when we consider how much improvement in this respect is needed in the metropolis. We believe that in London and other large towns, the saving in the destruction of clothing would at least pay for the proper cleansing of the streets without making any allowance for the saving of time and discomfort in locomotion.

The chapters dealing with the properties of materials and the construction of sewers, contain much useful information derived from the author's own experience and other sources, and may be consulted with much advantage by those engaged on works not only of this, but of other descriptions.

The much vexed question of sea outfalls and the influence of tidal currents on the selection of site is discussed, but it seems a pity that where ignorance and prejudice demand this mode of disposal, the author should not have laid stress upon the necessity of abstracting much of the solid matters held in suspension, thus much diminishing what is becoming an intolerable nuisance in many sea-side places. In giving so much importance to dilution with tidal water, it should have been borne in mind that this takes place in the direction of the breadth and depth of the volume of liquid discharged; but in the case of the solids floating on the surface, only in the former direction, and in both cases very slowly, as may be seen by an inspection of the metropolitan outfalls. It is impossible in the space at our disposal to notice the numerous details described and illustrated; the plates of all the more important are carefully drawn and well executed, no trouble being spared to make them thorough working drawings, while a sufficient number of woodcuts are introduced amply to illustrate the text. There are other books on this subject of a more popular nature, containing most of the information required by those who desire a general knowledge of the subject freed from too technical matters, but this is undoubtedly the best book hitherto published in this country for the student of practical sanitary science and for the engineer who requires a thorough treatment in detail of that branch of his practice.

THE NAPLES ZOOLOGICAL STATION

Mittheilungen aus der zoologischen Station zu Neapel, zugleich ein Reperatorium für Mittelmeerkunde. Erste Band, I. Heft. (Leipzig: 1878.)

SINCE the foundation of the Zoological Station at Naples, nearly one hundred naturalists have worked in the laboratory connected with it, and a goodly number of papers, which have resulted from their labours, are scattered through the biological periodicals of almost all the civilised nations of Europe. Gratifying as this success must be to Dr. Dohrn, the founder of the institution, he does not show himself inclined to repose on his laurels, but aims at still further extending the scope of the station by starting two publications in connection with it. One of these, of which we have the first number before us, is published in octavo size, and, as we learn from the preface, is intended for smaller papers, and general notes on the habits of animals living in the Aquarium, and other zoological topics. It will, moreover, be the medium for recording the systematic observations now being carried on by the permanent staff at the station. The second publication will be in quarto size, and will bear the title "Fauna u. Flora des Gulfes von Neapel und der angrenzenden Meeresbezirke." As its name indicates it will consist of fully illustrated monographs of the various groups of animals found in the Bay of Naples or adjoining seas. The parts may be purchased separately, or may be subscribed for by the payment of 1*l.* yearly. The contents of the first part of the "Mittheilungen" promise very well. Dr. Schmidtlein, who manages the public aquarium, contributes three short papers. One of them gives an interesting account of the habits of a large number of the various animal forms living in the aquarium. A second deals with the periodic appearances of pelagic animals in the Bay of Naples during the two past years, and the third is a list of the breeding times of the marine forms inhabiting the Neapolitan seas. Dr. Hugo Eisig, the general manager of the station, contributes a paper of very great importance on the segmental organs of the Capitellidæ. He shows that, in some species of this group, it is normal for several segmental organs to be present in a single segment, and that the number of these organs present in a segment increases in passing from before backwards. Dr. Eisig compares the segmental organs in Annelids with the segmental tubes in Vertebrata, and points out how closely the arrangement he has found in the Capitellidæ agrees with that described by Dr. Spengel in some Amphibia. There is an illustrated paper by Dr. Meyer on some points of crustacean anatomy, and two botanical papers by Drs. Falkenberg and Smitz. Dr. Dohrn himself communicates some observations on the Pycnogonidæ, in which he adduces a large amount of evidence to prove that the view as to the number of their appendages put forward by him some years ago, which was subsequently attacked by Semper, is, in all essential points, correct.

The number as a whole is very creditable to the zoological station, and we may congratulate the founder upon the continued prosperity of the institution, as evinced by its ever-increasing activity in all directions.

F. M. B.

OUR BOOK SHELF

Theorie der algebraischen Gleichungen. Von Dr. Jul. Petersen. xii. and 335 pp. (Kopenhagen, 1878.)

THE author tells us that this work owes its origin to the lectures he has given on the theory of equations at the Copenhagen Polytechnic School. In the preparation of it he has made use of J. A. Serrêt's "Cours d'Algèbre Supérieure," Todhunter's "Theory of Equations," and Jordan's "Traité des Substitutions." The first section treats of equations in general; Cap. I. general properties of algebraic equations; Cap. II. relations between the coefficients and roots; Cap. III. on elimination, describing the methods of Labatie, of Euler, of Sylvester, of Bezout, and of Poisson; Cap. IV. the transformation of equations. The second section is devoted to the algebraic solution of equations, viz., of the cubic (the methods of Hudde, Lagrange, Tschirnhausen, and Euler); of the biquadratic (the methods of Lagrange, Descartes, and others); the binomial equation, the Quintic, the breaking-up of a rational polynomial into rational factors, Abelian equations (a long chapter, including the division of a circumference into seventeen equal parts, and the reduction of the equation $x^{13} = 1$).

The third section is on the Numerical Solution of Equations: Cap. I., on the Separation of Roots (Descartes', Budan's, Rolle's, Sturm's, and Newton's theorems); Cap. II., the Calculation of the Roots in Numerical Equations (interpolation, of Newton's Method of approximation, also Lagrange's and Horner's methods). The fourth part, which treats of Substitution in four chapters: Cap. I. Substitution in General; Cap. II. (a long chapter, including the theorems of Lagrange and Cauchy, alternate, transitive, and intransitive groups, linear substitutions, &c.); Cap. III. Galois' Theory (this has not found its way into English text-books; Prof. H. J. S. Smith classes Galois, for early precocity, with Pascal and Gauss); Cap. IV. Applications of Galois' Theory (Abelian equations, the Galois and the Hessian equations).

This bare enumeration of the principal articles will show that this carefully-written treatise takes up some ground which has not yet been opened out or even alluded to in our common text-books on equations.

The Botany of Three Historical Records, Pharaoh's Dream, The Sower, and the King's Measure. By A. Stephen Wilson. (Edinburgh: David Douglas, 1878.)

THIS is a curious little book, the author's aim being to throw what light he can, either by comparison or suggestion, upon the probability of the plants referred to in these Scripture records being this or that species of cereal. Mr. Wilson seems to have given a good deal of consideration to each of the above questions, which, as he says in his preface, have only one bond of connection between them, namely, "a common basis in the botany of the cereal grasses." Notwithstanding the pains the author has evidently given to each of the subjects, we cannot but think that it will prove of but little value, the points advanced being by no means conclusive, and even the subjects in themselves being of small importance. It may be of some value to know whether the cereals "stand in the same alimentary relationship to mankind as they did when Joseph laid up the surplus of the plenteous years in the granaries of Egypt," because such a knowledge, if it could be proved, would show the progress made in developing the productive resources of these grasses, but whether the plant in Pharaoh's dream was *Triticum compositum*, or any other species of *Triticum*, is perhaps of little moment to mankind at the present time. As an illustraiton of what is to our mind mere speculation, we quote the following from p. 6:—"The wheats of 'Minnith,' in the Belka (Ezek. xxvii.) grown by the farmers of Judah and Israel, seem to have been in demand in the corn-market of Tyre. Probably Minnith was a remarkably good locality for wheat, so that when the husbandman in other districts got seed from this place they called it Minnith wheat."

The author's summing-up of this his first "Historical Record," namely, that "seven ears of corn came up upon one stalk," is that it "may be wrong, and probably is wrong, whereas the reading here proposed, that seven ears of corn came up upon one *stock*, while probably expressing the full meaning, can only err by defect, and must necessarily be right, as embracing an essential morphological fact common to all varieties of corn."

The Commercial Products of the Sea; or, Marine Contributions to Food, Industry, and Art. By P. L. Simmonds. With thirty-two illustrations. (London: Griffith and Farran, 1879.)

THIS is the first example this year we have had of a work antedated, in this case by more than two months. We cannot possibly see what is gained by this; is it meant to make readers of future years believe that a work was published a year later than it really was? If this is so, is it quite honest and respectable—to put it in the mildest possible form? When one gets over Mr. Simmond's extraordinary and often misleading style (for which we commit him to the tender mercies of the literary Dr. Birch), it is found that his work contains a great mass of useful and curious information, showing great diligence in the collection of facts, if not much skill in putting them together. Mr. Simmonds' work is divided into three parts, dealing with food-products obtained from the sea, marine contributions to industry, and marine contributions to art. Detailed accounts and statistics are given of the various fisheries of the world, under the first head; under the second head the sponge fisheries are dealt with, oils, isinglass, shells, seaweed, marine salt, and other products; and under part iii. tortoise-shell, mother-of-pearl, coral, and amber. It will thus be seen that the work has a wide range; it shows how much has been done, and how much yet remains to be done by science, to make the most of the products with which the waters swarm. Altogether the work contains much useful and interesting information in a handy form.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

A Question raised by the observed Absence of an Atmosphere in the Moon

IT is known that there is physical evidence of an absence of atmosphere in the moon. It would appear reasonable to conclude that the moon at one time had an atmosphere; for, according to the generally-accepted principles of Laplace, which make the sun and members of the solar system to have a common nebulous origin, it would seem very extraordinary if the particular offshoot of the common nebula which formed the moon had no gaseous constituent in it. If we admit, therefore, as probable that the moon at one time had an atmosphere, the question naturally suggests itself as to what has become of it. Various surmises have been hazarded in reply to this. I would venture to submit the following as a possible explanation, which, as far as it goes, is based on accepted principles:—It is known to be a demonstrated fact in connection with the established kinetic theory of gases that the velocities of the molecules of a gas vary among themselves from zero to an *indefinitely* great

velocity, *i.e.*, a velocity to which apparently no limits can be set. It is true that the molecules which in the accidents of collision among themselves acquire these enormous velocities, have been mathematically proved to be relatively few in number, the greater number of the molecules possessing velocities approaching the mean value. But it would seem to follow necessarily that molecules situated in the top stratum of any atmosphere, and which acquire these enormous (indeterminable) velocities, can sometimes overcome gravity, and be projected into space, so as not to return; as it is a known fact that only a *finite* velocity is required to effect this result. I have therefore to suggest that by this cause the moon's atmosphere has gradually disappeared. It is probable, no doubt, that it would take a vast period of time to have brought about this result, but we have an almost unlimited time at disposal. It might possibly be asked, How is it that the earth's atmosphere has not shared the same fate? In answer to this I would reply, first, that the value of gravity on the earth is known to be very much greater than on the moon, and second, that possibly (for aught we can tell) part of the earth's atmosphere may have thus disappeared; or the earth's atmosphere may be less dense at present than at one time, for anything we can say to the contrary. It would seem a curious fact to note in connection with this that there would be apparently grounds for inferring that the *constitution* or composition of the earth's (or any other planet's) atmosphere might have changed from the above cause, as evidently the lighter gaseous constituents, whose molecules acquire in the accidents of collision the highest velocities, would be first dissipated into space in the above manner. Thus, for example, any trace of that very prevalent constituent of the universe, hydrogen, that might have at one time existed in the earth's atmosphere, would have tended to become relatively rapidly eliminated, as the molecules of hydrogen are known to possess a normal velocity about four times as great as that of the constituent molecules of the earth's atmosphere.[1] It might be said that changes so great as those above indicated are scarcely realisable, but then it should be kept in view that we have an almost limitless range of time to draw on, and it is generally admitted to be very important to take the effect of time into due consideration, as, for example, is done in the case of geology, where mountain ranges are recognised by incontrovertible physical proof to have been carved out by the slow disintegrating action of rain and atmospheric influences prevailing through countless centuries. The gradual disappearance of an atmosphere (earth's or moon's) under the above cause might possibly be compared in slowness of operation to the other cosmical changes that the solar system is known to be undergoing, such as the gradual approach of the earth to the sun (and of the moon to the earth) through the friction of the material media in space, the accomplished stoppage of the moon's axial rotation by tidal action on its mass, and the gradual diminution of the earth's rotative velocity from the same cause. These slow changes, imperceptible in the range of human experience, become important in large time epochs, and it becomes desirable in the interests of truth, in tracing back events, to give due weight to these time epochs. In suggesting the above explanation, I have endeavoured to confine myself strictly within the limits of mathematically proved facts as a basis to draw deductions upon, and I should be glad to accept any criticisms that might be offered, either with the view to point out a difficulty or confirm the truth.

London, October S. TOLVER PRESTON

Remarkable Local Colour-variation in Lizards

THE following extract from a letter received some months since from Baron de Basterot, of Rome (a Fellow of the Geological Society of London), records an interesting case of local colour-variation, about which some of your correspondents may be able to give us further information:—

"Capri is a mass of the usual yellowish-white Apennine limestone, forming precipitous cliffs nearly all round the island. At its southern extremity are three high and nearly inaccessible rocks called I Faraglioni, one of which, pierced by a natural arch, has been frequently depicted by artists. Two of these rocks are completely detached from the mainland, and, I need hardly add, uninhabited.

"On the island, and on the first of the Faraglioni rocks which is connected with it, the lizards are of the usual species so common in Italy—coloured grey, mixed with more or less green. On the two outward Faraglioni rocks, which are completely separated from the shore, their colour is totally different. The back is of a blue so dark as to appear nearly black; the sides of a brilliant blue, like lapis-lazuli; the belly light whitish-blue, with a very slight tinge of green.

"An English gentleman whom I met in Capri had several of these lizards alive, which had become quite tame in the course of a couple of months. I believe he intends bringing them to England. He is of opinion that they differ in colour only from the lizards of the island, and that, though very different in appearance, they are the same species.

"Whether this be so, or whether they are specifically different, their presence on these isolated rocks and their total absence on the island is equally remarkable."

ALFRED R. WALLACE

Termites kept in Captivity by Ants

WHEN entomologising in Portugal in 1877, in the neighbourhood of Cintra, I found the nest of *Formica nigra* under a stone. On my turning it over there was, as usual, great consternation in the community, and I discovered that it was evidently caused by the fear lest a colony of *Termes lucifugus*, which the Formicas had enslaved, should escape. The Nigras instantly began seizing the Termites, driving them underground by the nearest orifices, in the meantime wrenching and pulling off their wings in the most unceremonious manner. I observed a large number of wings lying in heaps here and there in the nest as if this treatment had been practised before. In the nest there was also a great number of Termite larvæ. The great object of the owners of the "location" seemed to be to get these larvæ underground as speedily as possible. The ants fell on them with great impetuosity, seizing them anyhow and anywhere, dragging them against the most strenuous opposition (their behaviour strikingly contrasting with the meekness of their winged fellows) into the nearest apertures of the underground home. Very often this opposition resulted in a long and stern fight, in which the larvæ were often badly wounded, being deprived sometimes of their antennæ, sometimes of half their jaws, and not seldom killed outright. Occasionally, however, the larvæ were victorious, beating off the Formicas, in which case they (the larvæ) did not make off, but remained perambulating the nest. I saw one larva drawn at the end of a long fight by its antenna, while it strenuously held on to a small ball of earth which had proved a vain anchorage for its feet, for larva and clod together were dragged across the top of the nest (made by the impression of the stone) five or six inches, up the side, 1½ inch, and away among the grass, where, losing the ball of earth, it seized a stalk so firmly that its abductor could not drag it farther, whereupon, after reconnoitring the ground for a little distance the latter disappeared, but returned shortly with a companion, with whose aid the larva was detached. This done, the helper returned home while the abductor proceeded with his prisoner till lost to view in the grass, some twelve or fourteen inches from the spot whence it originally started.

In the same neighbourhood I watched for some time a nest of *Formica ligniperda*. An injured female was placed in the nest, but no assistance was rendered, while it crawled along towards the nearest orifice leading underground. At the spot where this individual was injured some of the fluid of its body which had oozed out was eagerly lapped up by the others; some even applied their mouths to the wounds on the body. During the operation of lapping the maxillæ were kept perfectly still, and the antennæ close to the side of the head "feel-feeling" the ground with the tips, as if to discover the spot where the liquid was to be found. Every now and then, however, they were extended at right angles to the body, as if to obtain a more general survey of things, and then immediately returned to their previous position. On several of those which were busy lapping I poured some spirits of wine. They instantly became stupefied, and for a time motionless. When in this condition they were

[1] The realisation of a possible diversity at a former epoch in the constitution and density of the earth's atmosphere raises rather a curious question in connection with the known diversity of the plants and animals that formerly inhabited the globe, as compared with those at present existing. It might be observed that admitting the possibility of the former existence of an atmosphere on the moon, it would seem to follow that an interchange of molecules between the two atmospheres (those of the earth and moon) must have taken place at one time to a certain extent under the above cause, though the considerably less value of gravity on the moon compared with the case of the earth would facilitate the passage of molecules away from the moon and render correspondingly difficult the passage in the reverse direction.

visited by many of their fellow colonists, who, having cursorily examined them, fell to touching them with their antennæ on the abdomen, reminding me much of a mesmerist making passes over a victim. The effect was almost electrical. I was surprised to see the incapables at once begin to rally. After stretching their legs and moving their antennæ they moved along slowly for one or two steps and then went along as if nothing had happened. Others came and drank of the spirit not quite evaporated, but did not seem to suffer any bad effects. I buried a member of the community as it was in the act of carrying off a larva. Although many came and looked on none took compassion or attempted to relieve their friend. A small heap of larvæ, however, which I pressed down into the soft earth with my pencil, thereby injuring some of them badly, was disinterred, and every individual carried into a place of safety.

A stranger placed in the nest was very soon set upon, and before long its head was travelling on a direction opposite to that of its abdomen. The headsman's reward was a long draught of blood from the severed abdomen.

On my turning over the stone at first, the larvæ were exposed, but were soon begun to be carried off. Some of the workers were certainly busybodies, fussing about, pretending to do a great deal, while in fact they were shirking their fair share of the household duties. They would rush at the larvæ, seize one and be off with it in a great hurry, but they had not gone far (not even always in the direction of the entrance) before they changed their minds, threw down their load to return for another helpless infant, which was treated in the same way, being carried generally in a direction contrary to the previous, and dropped down anywhere, sometimes beyond the limits of the nest altogether.

My observations with regard to ants dropping intentionally or jumping from small heights do not quite agree with Sir John Lubbock's, but they are not yet full enough to give in detail. I hope to have fuller opportunities for the investigation of the habits of this most interesting class in the Malayan Archipelago, whither I am now bound.

Meantime I hope these few notes may have some interest for the readers of NATURE. HENRY O. FORBES

S.S. *Celebes*, off Naples, October 18

Colour-blindness

HAS it been suggested that the traditional blindness of Homer may have been—in the absence among the ancients of a specific name for colour-blindness—*merely* the colour-blindness for which Dr. Pole makes out so good a case? To readers ignorant of Daltonism, blindness must have appeared the only explanation of a glaringly misapplied colour-epithet. It is at least clear that the author of the Homeric poems was not always blind in the modern sense of the word.

Brighton, November 1 CLEMENTINA BLACK

THE conclusion of Dr. Pole's valuable paper will doubtless stir up many to investigate the question whether or not dichromatism was the rule at an early stage of human vision.

Will you allow me to adduce, towards the solution of this question, the evidence of a literature, which though not nearly so ancient as the Greek, goes back further than that of many European nations. I mean the Irish. I find in some of the earliest works in that language an ambiguity in the application of adjectives of colour very similar to that noticed in the Homeric writings by Mr. Gladstone. *Glas*, for instance, is used, indifferently, apparently, for green, grey, and blue. *Uaithne* is used to indicate the colour of grass, and also that of the human eye. *Dearg* is employed to denote the colour of wine, and also that of clay. *Ruadh* (red) is similarly ambiguous.

182, Adelaide Road, N.W. EDMUND MCCLURE

Carrier-Pigeons

IN NATURE (vol. xviii. p. 682) it is stated that carrier pigeons are being "turned to useful account" in a new direction in Germany, for Consul Ward writes to the Foreign Office "that the successful results attained by the establishment of communication between the two Eider lightships and the Port of Tönning, in Schleswig, by these means has led to its organisation" elsewhere. This mode of communication is, however, not new, as carrier-pigeons were employed early in this century as a means of communication with the Bell Rock Lighthouse, as mentioned in my late father's "Account" of that work. The pigeons passed between the lighthouse and the shore—a distance of eleven miles in eleven minutes. The employment of these birds, however, was, I suppose, found to be more curious than convenient, for they have long since ceased to be employed. The pigeons were presented to the establishment by the late Sir Samuel Brown, R.N. THOMAS STEVENSON

Edinburgh

Globular Lightning

As the curious phenomenon known by the above name seems to be attracting some attention just now, I venture to send you the following details, which, though of rather ancient date, are still, owing to their startling character, very fresh in my memory.

I think it was in the year 1866, in the beginning of the month of August, that I was walking in the garden when the atmosphere became exceedingly oppressive (there had previously been a very long drought), and thinking by the appearance of the sky, which looked lurid and threatening, that a storm was coming on, I made for the house. As I was going up our front steps some rain-drops fell, which were the largest I ever saw. I had just reached the dining-room and was standing near the window, which looks north, when I saw a large ball of fire, which appeared to me, looking at it as I did from a distance, to be the size of a globe such as is used in schools, descend towards the earth. In descending it struck the church, which is immediately opposite our house, and brought with it a number of slates and part of a stone cross, making a terrific noise. There was a flash of lightning soon after, followed by a moderately loud clap of thunder, but nothing more. As there were not at that time any houses near to ours I did not hear the occurrence mentioned by any one. The noise, though extremely loud, was not at all like thunder. The illumination of the rooms by the ball of fire was seen by two other persons in the house. CHARLOTTE HARE

St. John's Road, Putney, S.W.

Speaking-Trumpets

THE antiquity of the speaking-trumpet may be proved upon far higher authority than that of the imaginative Athanasius Kircher. It is literally as old as the Pyramids. While examining Lepsius's great work upon ancient Egypt for my "History of Music" I noted two examples among the plates of the fourth dynasty of Egypt (see Lepsius's "Denkmäler," Dyn. 4, Abt. 2, Blätter 27 and 30). The Egyptian speaking-trumpets seem to have been some five feet or more in length, and too wide in diameter to have been blown by the mouth. They are conical, and lack the contraction near the mouth-end which is so observable in their war-trumpets.

WM. CHAPPELL

Toughened Glass

MY own experience supports the necessity for caution in using Bastie's toughened glass. Shortly after its introduction I had some graduated measures, and although they were sufficiently tough to bear the shock consequent on falling five or six feet to the ground, yet after a time some short scratches appeared on their surface, and these rapidly spreading till they nearly covered the whole of the glass, when but a slight touch was sufficient to make the measure fly into fragments. One placed on a shelf subject to rather rapid change of temperature, without any handling or apparent cause, broke up suddenly into tiny pieces, behaving, indeed, as if it were a Rupert's bomb.

Northampton, October 29 G. C. DRUCE

POTTERY AT THE PARIS EXHIBITION

THE extensive collections of pottery at the Paris Exhibition brought together from so many countries, is of high interest from a technical, as well as from an

art point of view. All that is now being done in pottery manufacture, all that has lately been achieved in the way of progress, has been here illustrated. An examination, even a rapid one, shows at once how far in advance of other countries England and France are.

Leaving all strictly art questions out of consideration, it is instructive to notice how the technical processes of manufacture impose limits on an artist's scope, and how these scopes have been widened by recent discoveries. It is not intended in this short note to do more than allude to the more important of these, and before doing so it is worth while mentioning that for domestic purposes English earthenware is still unapproached.

The *pâte-sur-pâte* decoration, so largely used in England and in France, is a good illustration of how a process in itself confines the artist's power within certain limits.

The nature of the ornamentation consists in applying by the brush, and modelling with tools, raised decorations of "paste," which is often, for the sake of artistic effect, in high relief. The paste is of much the same composition as the body on which it is applied, and requires a similar temperature to convert it into China, *i.e.*, 1,800° C. The colours which can be used for staining this paste must therefore also be capable of being produced at this heat, and the result is an entirely new range of ceramic colours. It is fortunate for the success of this style of decoration that the colours obtained are harmonious, of a subdued tone. They are quite unlike any that can be produced at a lower heat. Apart from the artist's manipulation, which may vary much in delicacy, the general effect of the production is almost wholly the natural result of the process, and is therefore not due entirely to the artist.

Another and distinct application of raised decoration is very largely represented in the French court. It was first used at Bourg-la-Reine some ten years ago, and is now made in many other localities. It consists of painting in clay on earthenware with pallet and brush in various gradations of relief, somewhat like impasto. The heat for firing is comparatively moderate, and the range of colours that can be employed is very wide.

The difficulties of painting *under glaze* are by degrees being overcome, and one manufacturer has, for the first time, produced gilding *under glaze*. The coloured glazes shown are rich and brilliant, and are well worth the particular notice of those who have paid attention to their production.

The organisation of the Sèvres manufactory and the fact that it is under the direction of a chemist of repute lead to expectations of discovery resulting from the research here carried out. And as a fact discoveries of no small value have been made of late years. Besides such discoveries as of compounds yielding new colours, there are some which take rank as new processes.

For example, the late François Richard, an artist on the staff of the manufactory, found that a large proportion of the enamel colours can be made which will bear a temperature of 600° C.—a higher temperature than has been hitherto supposed possible. This higher temperature now employed fuses and softens the glaze; the colours painted on it blend with it so that, on cooling, there is produced that softness and brilliancy hitherto characteristic of *pâte-tendre* decoration. This process has been named the *demi-grand feu*. A great benefit arising from this discovery is that many vases damaged in firing, which would formerly have been abandoned, can now be preserved, as the accidents which so often happen in firing can be repaired. Defects in glaze and colour can be concealed, as, during an exposure to this *demi-grand feu*, they are at melting-point, and new glaze, when added, becomes so fused that no line of junction is visible. This process also gets over a difficulty that had long been felt in decorating kaolin, or *pâte-dur*, china, with a pleasing result, as the colours were always crude and harsh, being *on* the glaze. When a soft effect was required recourse was had to the less durable and more costly *pâte-tendre* as a body on which to paint.

A new method for decorating porcelain where gold alone is employed has been invented by M. Réjoux. Formerly, when porcelain was decorated with gilding alone, the ornamentation was limited to the production of a pattern by the greater or less relief of the gold, and by its being burnished or left dead. Even the thinnest part of the gilding was opaque. No delicate effects could be produced, and the style was suited rather for an abundant display of barbaric wealth than for refinement of expression.

The new process enables the gilding to be put on so thinly and transparently that the most delicate effects of light and shade can be produced. It is, however, applicable only to vases of *gros bleu* colour, that is, to vases coloured with oxide of cobalt. Upon this ground the pattern is drawn with a pigment composed of oxide of aluminium. This is then subjected to a firing which fuses the oxides together, and a brown surface results. This surface is found to be more suitable than any other known for the reception of the gold paste, which can be laid on in a thin film, and then, further, by subsequent removal, can be made to give great transparency. This property of the brown surface is not destroyed by being tinted before the gilding, so that it is possible to tint it with different colours which shall show through. A further variation is very frequently obtained by changing the tone of the gold by mixing it with alloys. This admirable effect of transparency has not been produced by any other means, and the first piece made (with many subsequent) is exhibited.

Another of the processes invented at Sèvres is that of enamelling on *pâte-tendre* body. In this the colours are applied in powder in the same way as in enamelling on metal, and are fused at a very low temperature. They have more body and are more decided than are those produced by the older enamelling process. On some of the vases shown at the Exhibition the white ground seen is not that of the creamy *pâte-tendre* body, but the pearl white of the stanniferous enamel.

Other recent improvements which should find a place in a more technical and exhaustive notice have been illustrated at the Exhibition. It may be mentioned that other nations are striving to adapt some of the traditionally recognised styles and their method of manufacture.

We may, in conclusion, refer to a small but important exhibition of porcelain, *allant-au-feu*, useful for laboratory as well as for domestic use. It is a very good white, thin and hard, and will bear high temperatures if the changes are not too sudden.

SUN-SPOTS, ATMOSPHERIC PRESSURE, AND THE SUN'S HEAT

THE question whether the atmospheric pressure varies with the spotted surface of the sun was noticed by me in a paper on the Isobars within the British Isles. I could not, however, find any appearance of a decennial law in the yearly mean pressures: such a relation presented itself however in the varying directions of the isobars (*Proc.* Roy. Soc., 1877, p. 599). The yearly mean pressures in our latitudes are subject to large irregular variations, and several decennial periods would be requisite before these could be neutralised in the decennial means. As the irregularities are much smaller within the tropics, I did not fail to examine the yearly means for India which were in my possession at the time; and I found their variations very small and apparently without any relation to the decennial period. Mr. F. Chambers's interesting letter to NATURE (vol. xviii. p. 567) has

induced me to make a more careful study of the Indian observations at present before me.

Mr. C. Chambers had noticed previously the appearance of "a periodicity of very small range, which nearly corresponds in duration with the decennial sun-spot period ("The Meteorology of the Bombay Presidency." London, 1878, p. 12). It is obvious, whatever may be the results derived for a single station, that they can have little value if contradicted by those obtained elsewhere. I have shown that from Singapore to Simla the *daily* mean pressure varies in nearly the same way, the maxima as well as the minima occurring simultaneously or nearly so over all India (*Proc.* Roy. Soc., 1876, p. 24). Are then the *years* of maximum and minimum pressure also the same over India? The question has considerable interest independently of the existence of a decennial law. The following table contains the differences (Δ B) of yearly mean barometric height in *thousandths of an inch* from the means derived from the whole series of observations at each station. I possess at present unfortunately only an incomplete series for Trevandrum and the variations for 1841-48, and for 1853-64 are those from the means for each of these series of years, the barometers having been different. I have also added the differences of yearly mean temperature in *tenths* of a degree Fahr. from the means for each series of years during which the thermometer preserved the same position. The different series are separated by bars ——.

Year.	ΔB				ΔT

[1] There is an error of − 20 in the mean pressure given in the Madras observations for 1846 (here corrected).

[2] The variations for Bombay are taken from Mr. C. Chambers's "Meteorology of the Presidency of Bombay," pp. 11 and 32.

An examination of the quantities ΔB will show that all the principal deviations from the mean pressures occur in the same years and have the same sign at all the stations. The agreement of the variations for Trevandrum and Bombay in the six years 1859-64 is also very remarkable.

We see that there was a maximum of pressure in 1845 at the first three stations, a minimum at Madras and Bombay in 1849 (best marked at the former station), a maximum at the last three stations in 1855; a minimum in 1862, and a maximum in 1864 at Trevandrum and Bombay (the latter station showing a maximum also in 1868). These means, then, confirm in a general way for all India the result obtained by Mr. C. Chambers for Bombay,[1] that on the whole the mean atmospheric pressure is greatest near the epochs of minimum, and least near the epochs of maximum sun-spots, though there is no exact agreement between the two classes of variations from year to year.

And as the maximum pressure in 1855, shown at all the three stations, is considerably before the epoch of minimum sun-spots, it would be difficult to conclude that the epochs of one phenomenon lag on those of the other.

I consider this result to be one of very great importance. The exactness with which the mean barometric height has been obtained with standard instruments in first-class observatories, and the general agreement of the years of maxima and minima over India, give a weight to it which cannot be extended to an element so variable with locality as the rainfall. Although the barometric variations are not sufficient to explain those of the amount of rainfall (which is so different in different years, and for the same years at the different stations), yet they give a probability to the existence of similar laws in the variations of the meteorological elements which I believe was previously wanting.

Mr. F. Chambers's note was written chiefly with the object of deducing from the barometric means evidence that the emission of solar heat is greatest in years of most sun-spots. He says: "It is well known that in Central Asia the annual variation of the barometric pressure is greater than in any other portion of the globe, and it is universally admitted that this variation is due to the great variation of temperature between summer and winter, the barometer being low when the temperature is high, and *vice versâ*. If, therefore, the absolute heat of the sun is subject to considerable variations, we ought to find the barometric pressure in Central Asia responding to those variations just as it does to the annual variations of temperature; in other words, the summer barometric minimum should be lowest in those years when the sun is hottest, and the winter maximum should be highest in those years when the sun is coldest."

As I do not admit that the annual barometric oscillation is due to variation of temperature, I do not accept the conclusion: for though there is an apparent relation between the two, within certain geographical limits, and under certain local conditions (which are altogether independent of the heat emitted by the sun), there is no evidence that the one is *due* to the other. The true conclusion is that the local conditions which are favourable to a large oscillation of the monthly mean atmospheric pressure are favourable to a large oscillation of the monthly mean temperature: always within certain geographical limits, for beyond these the relation does not hold.

The subject is, I think, a very interesting one, and merits consideration. The relation of the oscillations of the monthly means will be seen from the ranges in the following table:—

[1] They also add another epoch, 1845.

	Lat. N.	Long. E.	Ranges of Monthly Means.[1]		
			Barometer.	Thermometer.	Bar. oscillation for 1°.
	° ′	°	in.	° F.	in.
Singapore	1 19	104	0·064	3·1	0·021
Trevandrum ...	8 30	77	0·112	4·8	0·023
Madras	13 4	80	0·299	11·8	0·025
Bombay	18 54	73	0·285	11·4	0·025
Pekin	39 54	117	0·777	52·8	0·015
Catherinenburg ...	56 50	60	0·310	64·8	0·005

I have not the means for Calcutta, but they confirm the relation shown for the other Indian stations. At Madras and Bombay the barometric oscillation corresponding to 1° F., attains a maximum, it has diminished considerably at Pekin, and at Catherinenburg it cannot be said to exist; for though the minimum pressure occurs near the epoch of maximum temperature, the time of maximum pressure may be said to extend over the seven months, October to April, during which the monthly mean temperature varies 37° F. Also at Hobarton (42° S.) the relation does not exist, though the range of monthly mean temperature is nearly 20°.

When we examine the individual cases in India more in detail, several facts present themselves which are opposed to any relation of cause and effect between the two phenomena. Thus, as regards the epochs of maximum of one variation, and minimum of the other, though both show considerable approximation to the solstices, yet there are some marked differences. At Bombay, where the barometric oscillation is greatest for a given oscillation of temperature, the epoch of maximum pressure *precedes* by nearly a month that of minimum temperature, while the epoch of minimum pressure occurs more than a month *after* that of maximum temperature. We find also that the relation of increasing oscillation of pressure with increasing oscillation of temperature which holds within certain limits for different places does not hold at the same place. That is to say, years of largest annual variation of monthly mean temperature are not years of largest variation of monthly mean pressure, and in some cases (as at Trevandrum) the range of monthly mean temperature may be nearly twice as great in one year as in another.[2]

No better example, however, of the relation of the two oscillations to *local* conditions can be given than that presented by the variations at two stations within sixty English miles of each other, Trevandrum within four miles of the sea on the western side of the Ghats, and Pallamcottah on the eastern side, nearly in the centre of the burning plain of Tinnevelly, and about 13′ north of Trevandrum. The monsoon, which commences in the end of April on the western side of the Ghats, is not felt at Pallamcottah; the annual range of temperature is thus much greater than at Trevandrum. The following are the mean ranges at Pallamcottah, derived from three years' observations by Col. W. H. Horsley, of the Madras Engineers, to whose kindness I owe them.[3] The Trevandrum ranges are placed beside them for comparison:—

	Lat. N.	Long. E.	Ranges.		
			Barometer.	Thermometer.	Bar. range for 1° F.
	° ′	° ′	in.	°	in.
Pallamcottah ...	8 44	77 48	0·241	10·3	0·023
Trevandrum ...	8 31	77 0	0·112	4·8	0·023

It will be seen that the ranges at Pallamcottah are more than double those at Trevandrum. The consequence of this remarkable fact is that, with an equal mean pressure at the two stations, the monthly mean pressure at Pallamcottah must be 0·065 inches greater in January and 0·065 inches less in June than at Trevandrum, and that the oscillations appear independent of the laws of equilibrium of pressure in gases.[1]

That the higher pressure in January at Pallamcottah does not depend on the lowness of the temperature in that month is proved by the fact that at Trevandrum, sixty miles distant, the mean temperature for January is more than 4° F. lower, and the pressure, instead of being higher on this account, is really more than half a tenth of an inch of mercury *lower* than at Pallamcottah for the same level.

The question which is now particularly before us refers to the yearly mean pressures. As the exact height (above sea-level) and index-error of Col. Horsley's barometer are unknown to me, and the direction of mean isobars can be determined with any accuracy only from observations with standard instruments, whose heights above the sea-level have been ascertained by levelling, I have employed for their determination observations made at the three observatories of Trevandrum, Madras, and Bombay, which fulfil the requisite conditions. The following are the mean pressures and mean temperatures at the stations; I have added a near approximation to the mean pressure at Singapore.[2]

		Barometer.		Thermometer.
		in.		
Singapore ...	...	29·904	...	80·3 Fahr.
Trevandrum	...	29·878	...	78·4 ,,
Madras ...	...	29·864	...	83·0 ,,
Bombay ...	...	29·846	...	79·0 ,,

When the latitudes and longitudes given previously are considered, it will be seen that the mean pressure *diminishes* from the equator at the rate of 0·003 inch for each degree of latitude; and that the yearly mean isobars run parallel to the equator (this conclusion is independent of the mean for Singapore). It will be seen also that the yearly mean isotherms do not lie parallel to the equator, their directions being determined chiefly by local conditions.

As the difference of latitudes of Trevandrum and Pallamcottah is only 13′, the difference of yearly mean pressures should, by the preceding result, not exceed 0·001 inches, while the mean temperatures differ by nearly 7° Fahr.[3]

We may conclude, then, that, whatever may be the apparent relation of the annual oscillations of pressure

[1] From means of five years' observations at Singapore and Catherinenburg, six years at Pekin, twenty-six years at Bombay, eight years at Trevandrum, and fourteen years at Madras.

[2] When the twenty-six years' observations at Bombay are placed in two groups, one with the largest, the other with the smallest annual variation of monthly mean temperature, I find the following ranges of the monthly means, derived in each case from the means of thirteen years' observations:—

Ranges of	Temperature.	Pressure.
	°	in.
Maximum	12·6	0·295
Minimum	9·9	0·289
Difference	2·7	0·006

The difference of ranges of pressure for 2°·7 at Bombay at the rate of 0·025 in. for 1° should be 0·067 in. The difference of pressure found is in the right direction, but is not one-eleventh of what it should be if the two were related as cause and effect, or even if the two were exact measures of variation of a single cause.

[3] The approximate height of Pallamcottah above the sea-level is 125 feet; that of the Trevandrum barometer being 193 feet.

[1] I do not enter at present into the consideration of the pressure-oscillation from 10 A.M. to 4 P.M., which appears to show a similar relation to the temperature-oscillation.

[2] The mean pressure at Singapore is corrected by + 0·020 in. for reduction to sea-level, a correction which it is believed is near the truth. The mean temperatures have received no reduction to sea-level at three stations as the heights are small, from 20 to 37 feet. That for Trevandrum has been *increased* by 0°·6 F. (height 193 feet) as an approximate reduction to the height of the other stations. The Madras barometric mean is corrected for index-error by − 0·005. See Introd. Madras Obs. 1851-55.

[3] Since by the annual oscillations 1° Fahr. is equivalent at both stations to 0·023 inches of mercury, if Mr. Chambers' analogy held, the yearly mean pressures should differ by 7 × 0·023 = 0·161 inches. The mean barometric pressure, corrected approximately for height at Pallamcottah, is very nearly the same as at Trevandrum. This is independent of the conclusions from the directions of the isobars.

and temperature, this relation does not hold for the yearly means; that is to say, it does not follow that a high yearly mean pressure should indicate a low yearly mean temperature, and *vice versâ.*

We may, however, arrive at a satisfactory answer to the original question by an examination of the variations of yearly mean temperature at the different stations. It must be remembered that the relation of the oscillations of monthly mean pressure to those of monthly mean temperature are deduced from the variations shown by a thermometer four or five feet from the ground. Does the thermometer at any station, or at a combination of stations, show a high yearly mean temperature with a low yearly mean pressure, and *vice versâ?* I have given the variations of yearly mean temperature (ΔT) at different stations, and it requires only a cursory examination of them to see that there is no such relation. There is, however, another fact of very great importance to be deduced from the values of ΔT, and that is, *the very great constancy of the yearly mean temperature* at all the stations, in spite of the known considerable variations in the amount of rain and of other meteorological results from year to year.

It may be asked how we can explain the facts which seem to relate the annual oscillations of the mean pressure and mean temperature with the independence of the variations of the yearly means. As an illustration we can suppose that with a strong wind and high temperature the height of the tide may be increased at a certain port, while a following north wind with low temperatures will diminish the height at low water; we should in such a case, especially if the temperature varied with the force of the wind, have a larger oscillation of the water with a larger oscillation of temperature: we would not, however, attribute the high tide to the greater heat; we can also conceive that the mean temperature might, in the case supposed, vary, but the level of the ocean would remain constant. Other illustrations might be suggested.

The conclusions at which I have arrived are:—

1. That the years of greatest and least mean barometric pressure are probably the same for all India.
2. Therefore, that the apparent relation to the decennial period found by Mr. C. Chambers for Bombay holds for all India.
3. That the annual oscillations of monthly mean pressure and monthly mean temperature have nearly a constant ratio in India.
4. That these oscillations depend on local conditions in the same latitude, at places quite near each other, which are independent of the heat emitted by the sun.
5. That the yearly mean isobars run parallel to the equator in India and are independent of local conditions.
6. That the directions of the yearly mean isotherms vary with the local conditions.
7. That there is no relation between the variations of yearly mean temperature and yearly mean pressure.

John Allan Broun

THE SIZE OF THE TIGER

In a work on the tiger, published in 1875,[1] I made the following remarks in reference to the size of the animal:—

"The size of the tiger varies: some individuals attain great bulk and weight, though they are shorter than others which are of a slighter and more elongated form. The statements as to the length they attain are conflicting and often exaggerated; errors are apt to arise from measurements taken from the skin after it is stretched, when it may be 10 or 12 inches longer than before removal from the body. *The tiger should be measured from the nose along the spine to the tip of the tail as he lies dead on the spot where he fell before the skin is removed. One that is* 10 *feet by this measurement is large, and the full-grown male does not often exceed this,* though no doubt larger individuals (males) are *occasionally* seen, and I have been informed by Indian sportsmen of reliability that they have seen and killed tigers over 12 feet in length. The full-grown male Indian tiger, therefore, may be said to be from 9 to 12 feet or 12 feet 2 inches, the tigress from 8 to 10 or *perhaps in very rare instances* 11 *feet* in length, the height being from 3 to 3½, or, rarely, 4 feet at the shoulder."

The point I now especially desire to elucidate as it has been the subject of discussion, but is one that has never yet been satisfactorily settled, is the greatest length the tiger attains.

Jerdon and others say that the average size of a full-grown male tiger is from 9 to 9½ feet in length; and Jerdon remarks that he has not seen any authentic account of a tiger that measured more than 10 feet and 2 or 3 inches.

I agree with Jerdon that 9 to 9½ or 10 and 2 or 3 inches are the lengths attained by the majority of tigers met with; but the occasional occurrence of tigers of upwards of 10 feet 2 or 3 inches (the authenticity of which is doubted) is attested by the evidence of several competent and reliable observers, who are quite aware that the measurements should be those of the animal as he lies where he fell, and before being despoiled of his skin, and that measurements of the skin after removal are deceptive.

I have taken some pains to ascertain the views of those who are most likely to be well informed on the subject, and I add the results of my own observations during considerable experience in Bengal, Oude, and Nepal; it would seem that the evidence wanted by Jerdon is forthcoming, and that tigers above 10 feet 3 inches, 11 feet, and even 12 feet, *are* occasionally met with, and *have been accurately measured.*

I may remark that it is very possible that like boars, and other animals, they may differ in size according to locality, food, and other conditions of life; and that such being the case, it is probable that tigers of one province or district may exceed those of another in size. Indeed I am inclined to believe that such is the case, and that therefore those who contend for the larger may be equally right with those who maintain the smaller measurements. I am rather inclined to agree with Mr. C. Shillingford, who suggests the possible progressive degeneration of the tiger; what, certainly, according to some, obtains in the case of stags in the continuously over-shot deer forests of Scotland, may also be going on in the tiger of the much-hunted jungles of India. However this is a mere suggestion, but be it as it may, the inches of the big tiger are, I think, an ascertained fact, for it can hardly be maintained that the authorities who vouch for it are either mistaken or misinformed, or that they do not know how to measure a tiger accurately.

Sir G. Yule, K.C.S.I., Bengal Civil Service, says: "I never had the luck to fall in with a 12-foot tiger; 11 feet odd inches I have killed twice or thrice. I have heard once, at least, of a 12-foot fellow fairly measured, and I cannot see why there should be any doubt as to the occasional occurrence of such exceptions to the general rule."

Col. George Boileau, Bengal army, says he killed a tiger at Mutearah, in Oude, that was well over 12 feet. He writes:—"I can speak positively as to the size of the tiger—his length was well over 12 feet before the skin was removed. He was, of course, quite an exceptional size, and unequalled, so far as my own experience goes, which extended over seventeen years of constant hunting after the species. My own experience of the size of tigers is that, in the female, the size runs from 8 feet to 9½ feet—the latter exceptionally large; in the male, from 9 feet to 11 feet; a well-grown adult tiger is

[1] Royal Tiger of Bengal, pp. 29, 30.

seldom less than 10 feet in length. I speak of hunting-grounds frequented by myself (chiefly Oude and Nepal Terai), for no doubt the size varies according to locality, abundance of food, and its reverse must of course produce their usual results."

Col. Sleeman, Bengal army, says:—"I don't remember having killed a tiger measuring more than 10 feet 6 inches in his skin, but I have seen skins of tigers 11 feet 6 inches in length, and once, at Dinagepore, in Bengal, over 12 feet. I have the skin of the largest tiger I think I ever saw, and it measures 12 feet 2 inches. This tiger was killed near Jubbulpore, in Central India, by an old Thakoor sixty years of age, and I preserve the skin as a trophy of native pluck and vigour in age."

The skins above alluded to were, no doubt, stretched, and therefore do not prove more than that they were taken from large animals, which may have been probably between 10 and 11 feet in length!

Col. J. Macdonald, Bengal army, Revenue Survey, says:—"The largest tiger I have ever measured out of seventy was 10 feet 4 inches, and out of all these only three have touched 10 feet. But I do believe that tigers have exceptionally reached 12 feet." "The skin of a tiger ten feet in length, as he lies dead, would stretch to nearly twelve feet, but after curing it returns to nearly its normal size. I have often measured the distance between a tiger's marks on the ground; average and large animals are from 4 feet 4 inches to 4 feet 8 inches; well! I once found marks 5 feet 10 inches apart, this must have been the mark of a gigantic beast—the breadth of the impression of the fore paw, and the depth of the impression, showed his great size and weight. This was in the Sunderbunds. Mr. M., of Morel-Gunge, told me that once when going through a narrow creek in the Sunderbunds, he saw a stupendous brute, far exceeding in size anything he had before seen in tigers or could have believed possible. The heaviest male tiger I have seen weighed 448 lbs., the lightest, a tigress, 242 lbs."

The Hon. R. Drummond, B.C.S., late Commissioner, Rohilkund, says:—

"I have never seen a 12-foot tiger. The largest I ever shot was 11 feet 9 inches as he lay on the ground immediately he was shot, and before being padded. I measured him because I was struck with his large size."

F. B. Simson, Esq., B.C.S., says:—"I have killed or been at the death of about 180 tigers; I never actually handled one 11 feet long, but I fully believe that they reach that length occasionally, and every now and then a monster is found. The largest skins by far I have seen, came from China. I give you the exact measurements of several I have killed and fairly measured immediately after death, and before they were padded with dates:—

			Tigers' length. Ft.	In.	Height at Shoulder. Ft.	In.
1855	October	15	9	5	3	6
1856	February	13	10	4	3	8
,,	,,	11	10	11	3	7
1858	March	15	9	1	—	
			Tigresses' length.			
1855	October	14	8	8	3	3
,,	,,	13	8	5	3	5
,,	,,	19	8	11	3	5
,,	November	22	8	10	3	3
1856	October	6	9	4	3	10½
1857	February	8	8	10	3	4

"All these were killed on the churs of the Megna, between Backergunge and Noakhally. In later years I killed tigers in Purneah, Docca, Mymensingh, and Assam, but their exact dimensions were not recorded. I do not remember any exceeding generally in size the measurements I have given. I once killed a tiger which stood almost 4 feet at the shoulder.

"I have often been referred to about hogs. I have taken about 900 first spears, and hunted in nearly every zillah in Bengal, but I never speared the boar that would not have walked under a standard of 3 feet 3 inches. This statement has disappointed many; but the facts are at your service, and you may use my name to authenticate them when you choose."

Major-General Sir H. Green, K.C.S.I., C.B., Bombay, says:—"The biggest tiger I was ever at the killing of was in 1848, near Surat, and it measured, *pegged out*, 12 feet 4 inches. I heard by last mail from Claude Clerk at Hyderabad, who said he had just killed, to his own gun, the biggest tiger *he* had ever seen, as it measured 11 feet 6 inches *before* skinning."

Sir H. Green also writes:—"I inclose a letter from Col. Stewart regarding tigers, and I have made many inquiries about them since, and there can be no doubt that a 12-foot tiger is very rare, although I have no doubt there are instances of that size having been exceeded. I find, by reference to my journal, that I have a record of some I have killed, and that the one I mentioned as 12 feet 4 inches, pegged out, measured, *before* skinning, 11 feet 11 inches. Measures before skinning:—

11 feet 11 inches.
10 ,, 11 ,,
9 ,, 9 ,,
9 ,, 6 ,, .—Tigress.
9 ,, 3 ,,
8 ,, 6 ,, .—Tigress; pulled down my elephant."

Col. D. G. Stewart writes:—"I have never seen or heard of a *bona fide* 12-foot tiger, *i.e.*, as he lay in his skin. The largest I ever saw or killed was, as he lay, 11 feet and ¼ inch. I have personally measured eighty tigers or more of my own shooting, and the dimensions I have given are those of the largest of my victims. I saw a skin in San Francisco, of a Chinese tiger, which might have been 12 feet long in life. I never saw anything Indian to approach it. The Chinese skin was fairly treated, had breadth as well as length, the fur was long and soft. The average size of large males in the Central Provinces I found to be 10 feet 6 inches to 10 feet 8 inches; the tail had a good deal to do with the last two or three inches. The largest tigress I killed was, I think, 9 feet 3 or 4 inches, but I speak from memory. Of two males the girth of the fore-arm of one was 48 inches, the average being 32 to 34 inches. One of the most remarkable measurements is that of the tail where it joins the carcass. I have repeatedly found it in males 12 inches."

The Hon. Sir H. Ramsay, K.C.S.I., C.B., Commissioner, Kumaon, writes: "I have always understood that Bengal tigers are larger than ours in the north-west. The largest tiger I ever killed measured 10 feet 5 inches, and I consider anything above 10 feet a large tiger; a tigress very seldom gets beyond 9 feet. I have heard of Bengal tigers measuring 12 feet. G. tells me his father, a Bengal civilian, shot a tiger that measured 12 feet 4 inches, but I never shot in Bengal."

Mr. C. Shillingford, indigo-planter, Purneah (with whom I have shot many tigers) says: "My experience extends over thirty-five years, during which I have shot more than 200 tigers. In 1849 I shot one of the largest tigers I have ever seen, with a party of four. He measured, *as he fell*, 12 feet 4 inches, was very old, and his marks had become faint; the hair was short, like that of a greyhound. I shot another tiger which measured, as he fell 11 feet 10 inches, and another in 1855, 11 feet 4 inches; several of 10 feet 6 inches and 10 feet. The majority of male tigers seldom exceed 10 feet, and many attain only 9 feet 8 inches or 9 feet 10 inches."

Cumming says he has shot a few over 11 feet, and gives three instances—one at Rohinipore, 11 feet 4 inches: one at Kaliastrich in 1865, of 11 feet 2 inches; and another at Gour in 1871. My nephew has also shot one or two over 11 feet.

I think these very large tigers are rare, and are only to be found in the Ganges churs; I am also inclined to believe

that they are degenerating, as I have not shot large ones for several years: or it may be that there is a keener set of sportsmen now-a-days, and no sooner is a tiger heard of than he is shot. The tigresses are seldom over 8 feet, though I have known some that attained 9 feet to 9 feet 6 inches. Cumming says he has seen the claw-marks of a tiger on a tree 18 feet high. The men who are difficult to convince about the large tigers are those who have shot them in hills and rocky places, and those tigers are of a different class and seldom grow large."

Major Bradford, C.S.I., of the Political Service, says: "10 feet 5 inches was the largest tiger I ever saw; but I sent the question to Martin and inclose his reply and the inclosures to it. I remember hearing of the immense tiger White speaks of."

Col. C. Martin, C.I. Horse, says he shot a tiger at Putulghur 10 feet in length, and alludes to a large tiger shot near Goona by Mr. White, which was measured by Mr. Angelo, and is described as follows by the latter gentleman: "I can remember, beyond all doubt, the length was 12 feet 4 inches from tip of nose to tip of tail; 2 feet 2 inches from ear to ear! The direct breadth of wrist 8 inches, spread of foot 10 inches, heel to withers 4 feet, and the tail was 3 feet in length."

These measurements were recorded in the *Delhi Gazette*, but there is some doubt as to their accuracy; so that they may hardly be regarded as proving more than that the tiger was a very large one. Col. Martin says, in a subsequent letter, "W.'s tiger, which I had always thought 12 feet 4 inches, is no longer to be relied on for scientific inquiry, though it probably exceeded 10 feet."

Lieut. James Ferris, B. Army, says: "I have had a good deal of experience, as I have shot in the Central Provinces, and for several years in Oude and Nepal. The largest tiger I know of was shot by Wilkinson, in 1873, in Nepal, he measured 10 feet 4 inches from tip of nose to tip of tail. Wilkinson, who has shot more tigers than most men in India, told me this was the largest he had ever seen; the largest tiger I ever shot myself I got the same season in Nepal; he measured 10 feet 2 inches—he was considered a monster. The tigers in Lower Bengal may be larger, but in the Central Provinces they are certainly smaller; it depends a great deal on how the tiger is measured."

Gen. Ramsay, Bengal Army, says: "The largest tiger I ever saw I shot in conjunction with Col. Stewart, a fine old sportsman, who died many years ago at Benares. The tiger was not found for some days, when he was discovered dying from loss of blood and starvation. The skin was removed, and measured 12 feet from the nose to end of tail." This skin was no doubt stretched. "A tiger of 10 feet 6 inches is a very fair sized tiger. Tigresses seldom grow so large." General Ramsay adds: "My friend Col. H. Shakspeare writes me that 'the two largest tigers he ever killed were, when brought in and measured, 11 feet 8 inches and 11 feet 6 inches respectively—the latter a tigress.' He does not think he has ever seen larger ones. There probably are tigers that measure 12 feet or more, but they would be very rare."

Mr. F. Buckland has kindly given me the following extract from his "Curiosities," 1866, in regard to a tiger shot by Col. Ramsay, who says that he and Major B. shot a tiger at Huldwana, in the Kumaon Terai, that they estimated to be about twelve years of age, and was of the following dimensions:—

	ft.	in.
Length from nose to end of tail	12	0
,, of tail	3	9
Height from heel to shoulder	3	7
Girth of body behind shoulder	5	3
,, forearm	2	10½
,, neck	3	7
From ear to ear	1	6½
Length of upper canines	0	3
,, lower ,,	0	1¾
,, claws	0	3

On referring to some of my own tiger shooting notes I find that I have recorded the following measurements:—

Oude Terai, 1855

		ft.	in.
1.	Tiger	9	5
2.	,,	8	0
3.	Tigress, very large, pregnant with five cubs, measurement not preserved.		
4.	Tiger	10	0
5.	Tigress, large, but measurement lost		
6.	Tiger	9	0
7.	Tigress	8	10
8.	,,	8	11
9.	,,	8	9
10.	Tiger, cub	5	9
11.	,,	9	7
12.	,,	9	11

Oude Terai, 1857

		ft.	in.
13.	Tigress	8	0
14.	Tiger	8	3
15.	Tigress, with three cubs	8	10
16.	Tiger	Lost measurement.	
17.	Tigress	ditto.	
18.	,,	ditto.	
19.	Tiger	ditto.	
20.	Tigress, very large, pulled G.'s elephant down, lost measurement.		
21.	Tiger killed in Hangua (drive) from a tree, very large.		

Maldah, Bengal, 1870

22.	Tigress	Measurements lost.
23.	,,	

Ulwar

24.	Tiger	Measurement lost.

Purneah, Bengal, 1869

		ft.	in.
25.	Tigress	8	2
26.	Tiger	10	0
27.	Tigress	8	7
28.	,,	Measurement lost.	
29.	,,		
30.	,,		
31.	Tiger	10	8

Purneah, 1871

		ft.	in.
32.	Tigress	9	0
33.	,,	7	6
34.	,,	7	8
35.	,,	8	8

Oude and Nepal, 1871

		ft.	in.
36.	Tigress	8	9
37.	Tiger	9	7
38.	Cub	5	5
39.	,,	5	8½
40.	Tigress	8	7
41.	,,	8	6
42.	Tiger	9	6
43.	Tigress	8	8
44.	Tiger	10	6
45.	,,	7	0
46.	Small cub		
47.	Tiger	9	4
48.	Tigress (I killed her with a single bullet in the neck)	8	11
49.	Her three cubs.	6	11
50.		6	5
51.		6	10

These are all the notes I can lay my hands on at present. The largest tiger was 10 feet 8 inches, the largest tigress, 9 feet. Both were Bengal Purneah tigers. My own experience, therefore, confirms so much of Jerdon's estimate as that the tiger averages from 9 to 9½ feet, the tigress between 8 and 9 feet; but that which he and others doubt, viz., that tigers do occasionally attain the length of upwards of 10 feet 3 inches and even 11 feet or 12 feet, and the tigress up to 10 feet or even more, is

conclusively attested by the evidence of the gentlemen whose statements I have quoted.

I am indebted to Sir Dighton Probyn for an interesting letter from Capt. Gerard, of Goona, a high authority on Indian felidæ. He expresses his belief that tigers seldom if ever exceed Jerdon's measurements, a tiger of 10 feet 1 inch being the length of the largest he has ever killed or seen. He refers to examples of large tigers described by various observers, but he doubts the accuracy of the measurements, which he thinks may have been unintentionally exaggerated. His own experience is very large, his accuracy as an observer well known, and his opinion consequently of much value; but it is hardly sufficient to invalidate that of others who are no less competent to note and record facts, and who certainly give a greater length, as the extreme growth of the tiger, than that within which Capt. Gerard limits him. The matter then stands thus: Mr. C. Shillingford, Col. G. Boileau, and Sir C. Reid,[1] vouch for tigers of over 12 feet. The same gentlemen, with Sir H. Green, Sir G. Yule, the Hon. R. Drummond, Col. D. G. Stewart, Mr. Cumming, and Col. Shakespeare vouch for tigers of 11 feet and upwards. The above, with Col. J. Sleeman, Sir Joseph Fayrer, Mr. B. Simson, and the Hon. Sir H. Ramsay vouch for tigers of 10 feet 5 inches and upwards, all from measurements taken before the animals were skinned. Unless these gentlemen, all of whom are accustomed to shoot and measure tigers, were *mistaken*, the question of length may, I think, be regarded as decided beyond dispute.

In conclusion, after thanking sincerely those gentlemen who have given me information derived from their own experience, I would just say that the mere length of a tiger is not necessarily an indication of its real size. The tail is included in the measurement—so tiger hunters have ruled that it shall be—but the tail is a somewhat variable element; in some it is long, in others short, and it is quite possible that a 9-foot 6-inch tiger with a short tail may be heavier, stronger, and larger than a 10-foot tiger with a long tail. No doubt anything over 10 feet is very large, and those of 11 or 12 are rare and exceptional, even though part of their great length may be assigned to an immensely long tail. But I think that, while making all allowances for errors of measurement—which doubtless are not uncommon, though unintentional—there is still sufficient evidence from accurate measurements to show that tigers may exceed 10 feet 3 inches, and that a few—perhaps rare and exceptional instances—do exceed even 11 and 12 feet.

J. FAYRER

THE TELEPHONE, ITS HISTORY AND ITS RECENT IMPROVEMENTS[1]

II.

IN the preceding article we traced the history and development of the magneto-telephone. This instrument, even if it served no other purpose, has given to physicists a galvanoscope of surpassing delicacy. In the columns of this journal (vol. xvii. p. 343) Prof. Forbes showed how the feeblest thermo-electric currents could be detected by its means, whilst the subsequent discovery of the microphone was but another application of the same fact. This latter instrument and the early history of the carbon telephone we now propose to consider.

In the spring of the present year Mr. W. H. Preece startled every one by announcing that Prof. Hughes, the well-known inventor of the type-printing telegraph, had discovered that a couple of bits of charcoal, or a few fragments of metal in loose contact, when in circuit with a telephone and a voltaic cell, were able to reveal the faintest tremor or even to transmit the sound of the voice itself. Universal interest was excited by this discovery; a direct transformation of sonorous vibrations into electricity was supposed to have been discovered, but soon it became apparent that the explanation originally suggested was untenable, and that the true theory of the microphone was to be found in minute variations of current strength. The quivering of the loose fragments produced variable degrees of contact or of pressure, and the marvellous sensitiveness of the magneto-telephone revealed these otherwise inappreciable fluctuations in the resistance of the circuit.

On account of its sensitiveness, the microphone has been suggested as likely to be of use in auscultation.[1] M. du Moncel gives a form of stethoscopic microphone made by M. Ducretet, and shown in Fig. 2. The microphone pencil, C, rests upon a lower plate of carbon, P, which is adapted to a caoutchouc capsule, T, and this again is connected by a flexible tube to a second capsule, T′, which can be applied to different parts of the body of the patient. Although the sensibility of the microphone can to some extent be regulated by the counterpoise, P O, yet still the objection to this apparatus is its over sensibility, for it reveals every noise or tremor, so that it is difficult to distinguish one sound from another. It is not impossible, however, that this or some other arrangement of the microphone may ultimately be found to yield important results in the hands of a physician who has made himself skilled in its use. At the same time we must bear in mind that, after its employment in a surgical case by Sir H. Thompson, the large expectations that were formed of the microphone as an exploring instrument in surgery have not as yet been fulfilled. We are not aware whether the microphone has been tried by seismologists, or by military men to detect the mining operations of an enemy, though we should fear the same causes that operate against it elsewhere might also occur wherever it is employed. The disturbances to which the instrument is subject are most conspicuous when the microphone is used, as it can be, to transmit speech. Nevertheless a particular arrangement, designed by Mr. Hughes (Fig. 3), gives fair results. The two fragments of carbon are shown at C D, the upper one being attached to a light metal arm A B, controlled by a spring R, the tension of which is regulated by a screw *t*. The whole is inclosed in a light wooden box H I G, surrounded by a second box M J L, the end of which is left open. A single carbon only, may even be used, touching the metal arm, as is shown at E. In this case the carbon is supported by a strip of paper gummed to the bottom of the box. Loud as is the articulation transmitted by means of this arrangement, the noisy roar which accompanies it, from tremors picked up by carbons, render many words quite inaudible in the receiving telephone. So far, in fact, the microphone has not proved a practical instrument; it seems, however, likely to become a useful adjunct in physical or physico-chemical researches. In any case science is indebted to Prof. Hughes for first making known an entirely novel, simple, and delicate instrument for the detection of minute mechanical motions.

We say first making known, for some twelve months before Prof. Hughes published his description of the microphone, an arrangement designed by Mr. Edison was singularly like the microphone in its extreme delicacy to the minutest tremor. A couple of inches of silk ribbon rubbed with plumbago and made stiff with gum, was laid upon two metal supports joined in circuit with a telephone and a small battery. Such an arrangement not only de-

[1] Since writing the above I have been informed by General Sir C. Reid, K.C.B., Bengal Army, that he has shot, and measured before the skin was removed, in the Dhoon a tiger of 12 feet 3 inches.

[1] "The Speaking Telephone, Talking Phonograph, and other Novelties," by G. B. Prescott. Illustrated. (New York: Appletons, 1878.)—"Le Téléphone, le Microphone, et le Phonographe," par Le Comte Th. du Moncel. (Hachette, 1878.) Continued from vol. xviii. p. 700.

[1] *Apropos* of the microphone a literary friend sends me the following extract from an ancient Turkish tract containing an exposition of the Moslem creed:—"He (Allah) hears alike the loudest and gentlest sounds and sees all things, even the walking in a dark night of a black ant on a black stone, and hears the treading of its feet, and this without eyes or ears."

tected the slightest vibration but was capable of transmitting speech with remarkable loudness. Although this result has hitherto been unpublished, an application of the same principle was made by Mr. Edison in his "carbon relay," a reprint account of which was published in the *Telegraphic Journal* for July 1, 1877, and the simple form of this relay (Fig. 4) resembles in construction and in principle the so-called hammer and anvil microphone. Edison's carbon rheostat, lately illustrated in our pages, also depends upon the same principle, namely, the compression of a semi-conductor, such as carbon, increasing its conductivity, a diminution of pressure increasing the resistance. It is true that it has been suggested that a rheostat of this kind was made by M. Clérac in 1865, but so far as we have been able to ascertain, no mention is made of varying pressure in the use of Clérac's instrument, but simply the difference in the resistance of columns of plumbago of varying length.

The curious effect of pressure on the electric resistance of semi-conductors was noticed so long ago as 1856 by M. du Moncel, who wrote as follows in the second edition of his "Exposé des Applications de l'Electricité" (vol. i. p. 246) :—"Une chose assez curieuse, et qui paraît être au premier abord en contradiction avec la théorie que l'on s'est faite de l'électricité, c'est que la plus ou moins grande pression exercée entre les pièces de contact des interrupteurs influe considérablement sur l'intensité du courant qui les traverse. Cela tient souvent à ce que les métaux de l'interrupteur ne sont pas toujours dans un état parfait de décapage au point de contact, mais, peut-être aussi à une cause physique encore mal appréciée." Subsequently, in an elaborate memoir on the electric conductivity of bodies, the same distinguished author wrote :—"La pression exercée sur les electrodes joue un grand rôle sur la conductibilité de celui-ci quand il est susceptible d'une certaine compression, comme les bois, les corps mous et pâteux et ceux qui sont réduits à un grand état de division." In 1873 Edison states (Prescott, p. 223) that he independently discovered "the peculiar property which semi-conductors have of varying their resistance with pressure while constructing some rheostats for artificial cables, in which were employed powdered carbon, plumbago, and other materials in glass tubes."

In January, 1877, Edison states that he first applied to *telephonic* purposes the effect of pressure on carbon. It will be remembered that the principle of Gray's telephone was the variations in the resistance of a liquid, proportional to the motions of a diaphragm vibrated by the voice, but that the decomposition of the liquid by the current introduced practical difficulties in the working of this arrangement. Casting about for a means of overcoming this difficulty, Edison recalled his early observations on the electrical properties of carbon, and, encouraged by his preliminary trials, was led onwards step by step, his unwearied efforts being at last crowned by the construction of his carbon telephone, towards the close of last year. In another article we shall trace the evolution and present achievements of the carbon telephone, an instrument which we believe is destined to have a great future.

In conclusion, it is interesting to note that just as Gray and Bell were both led to the discovery of the principle of an articulating telephone through working at the important problem of multiple telegraphy, or the simultaneous transmission of several different signals on one wire, so, too, Edison travelled in the same direction. In Prescott's work he writes: "Some time in or about July, 1875, I began experimenting with a system of multiple telegraphy which had for its basis the transmission of acoustic vibrations." His transmitters were a chord of tuning-forks maintained in vibration by the action of a current; the current not being interrupted at each vibration, but made to vary in strength: his receivers consisted of electro-magnets acting upon iron diaphragms, which closed the end of a series of resonant tubes. In practice difficulties arose, but the system contained two important features.

These were, first, the employment of undulatory electric currents, an electrode attached to one prong of the transmitting fork being made to vary the resistance of the circuit by vibrating in a vessel of water, an idea which Edison claims to have patented as early as 1873; and the second is the use of an iron diaphragm and adjacent electro-magnet as a receiver. Substituting a membrane moved by the voice, the transmitter becomes the same as that patented by Gray in 1876, and the receiving instrument is similar to that used in the magneto-speaking or Bell's telephone. Hence, if these facts are unassailable, and the latter is at present the subject of litigation in America, to Edison is also due the happy inspiration of first using a thin iron diaphragm as a receiver. At the same time Edison, in a recent letter to the present writer, remarks, "Bell had the merit of discovering such a receiver would act as a transmitter," and likewise in

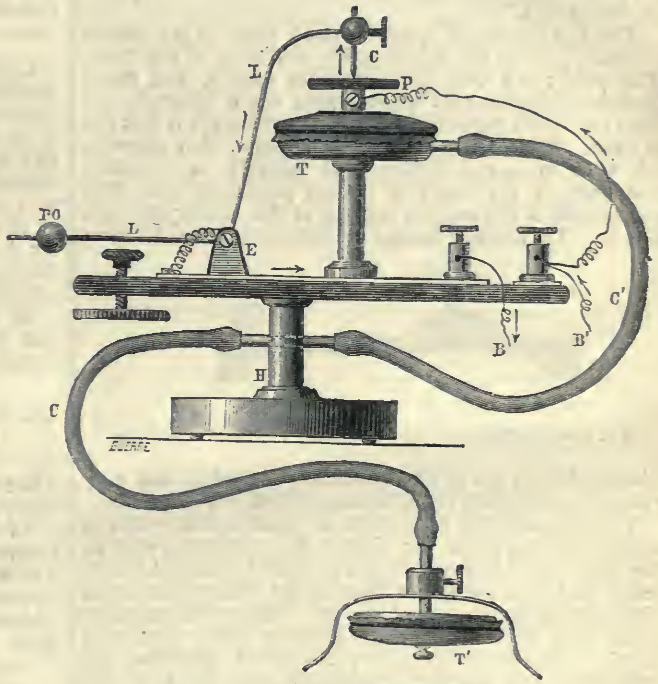

FIG. 2.—Ducretet's stethoscopic microphone.

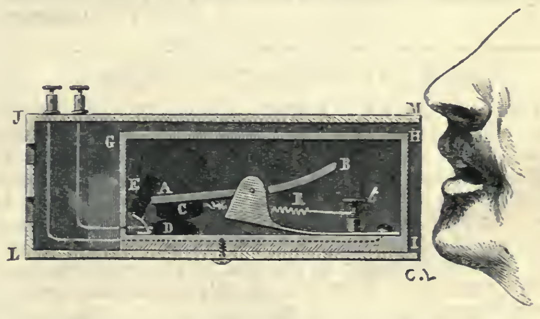

FIG. 3.—Hammer and anvil microphone as arranged for transmitting speech.

Prescott's book, Edison distinctly says: "I can lay no claim to having discovered that conversation could be carried on between one receiver and the other upon the magneto-principle, causing the voice to vibrate the diaphragm. . . . My first attempts at constructing an articulating telephone were made with a Reis transmitter and one of my resonant receivers. My experiments in this direction, which continued until the production of my present carbon telephone, cover many thousand pages of manuscript."

This last incidental remark, which there is no reason to doubt, reveals the indefatigable character of the man. The public see only the successful results, and many doubtless imagine that these spring ready accomplished from the fertile brain of Mr. Edison; the truth is just the reverse. It is a trite, but true observation, that successful work in any direction, and notably in scientific discovery, is the result of patient persistent toil. The public look at the nugget, but not at the labour that has won it. The fields of science are now so well trodden that

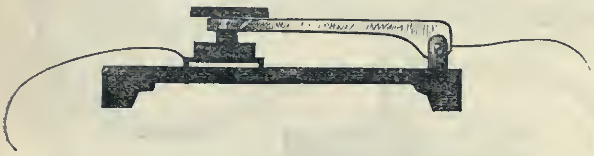

FIG. 4.—Edison's pressure relay resembling one form of microphone.

discoveries are not to be accidentally picked up, but only reward those whose quest is most skilful and diligent.

The extraordinary succession of valuable discoveries in applied science which Mr. Edison has made can only be the offspring of incessant work, profound technical knowledge, and that ready resource under difficulties which characterises a mechanical genius. The conditions under which such a man works are different from those of a purely scientific investigator; the latter publishes his researches and thereby establishes his claim to the priority of the work he has done; the former can publish nothing till the end he has in view is achieved, and the pecuniary benefit accruing from his labours secured by legal processes. And because the reward sought in the two cases is very different, the investigator must often expect to see others reaping the benefit of applications that may be made of his observations, and the inventor ought not to grumble when he finds others claiming credit for work he may previously have done, but for his purpose found it necessary to keep by him unpublished.

W. F. BARRETT

OUR ASTRONOMICAL COLUMN

THE LATE SOLAR ECLIPSE AT WATSON'S STATION.—Prof. Watson made such excellent use of the brief period of totality in the eclipse of July 29, that it will not be without interest to record the circumstances under which he observed. In a communication to M. Mouchez he gives for his position at Separation, Wyoming Territory, latitude 41° 45′ 50″, longitude 2h. 1m. 36s. west of Washington, corresponding to 7h. 9m. 48·1s., west longitude from Greenwich. Prof. Newcomb's corrections to Hansen's place of the moon at this time are − 0·63s. in right ascension, and + 3·3″ in declination; whence if we take 10h. 24m. Greenwich M.T. for a special calculation, we have for the position of the moon, R.A. 8h. 38m. 11·96s., decl. + 19° 5′ 59·3″. Combining this with the sun's place from Leverrier's Tables and the *Nautical Almanac* semi-diameters, there results

Beginning of total eclipse, July 29	...3h. 13m. 32·5	Mean times
Ending	...3h. 16m. 24·0	at Separation.

Thus the duration of totality was 2m. 51·5s.

If for the *Nautical Almanac* values we substitute Leverrier's semi-diameter for sun and deduce the semi-diameter of the moon from her horizontal parallax with Burckhardt's ratio, we find the times of beginning and ending of totality are respectively 3h. 13m. 32·0s. and 3h. 16m. 24·5s., showing a duration of 2m. 52·5s.; we may therefore take 2m. 52s. for the interval which was available to Prof. Watson in his search for intra-mercurial planets. The middle of totality occurred at 3h. 14s. 58·3s. M.T. at Separation, or at 11h. 44m. 41·9s. sidereal time, when the sun's altitude was 44½°, and his hour-angle 46½° W.

CALCULATION OF EXCENTRIC ANOMALIES.—The number of bodies in the minor planet group is now approaching two hundred, yet so far as their orbits have been satisfactorily determined only two or three out of this number have the angle of excentricity, as it is termed, or $\sin^{-1}e$, greater than 20°, which corresponds to $e = 0·342$. More than ten years since Mr. Godward, of the *Nautical Almanac* Office, prepared some tables for the direct computation of the excentric anomaly from the mean to this limit of excentricity. His process is as follows:—

In orbits where the excentricity is not great, M, u, and v being the mean, excentric and true anomalies respectively, and ϕ the angle of excentricity—

$$\tan \tfrac{1}{2} v = \tan^2 (45° + \tfrac{1}{2}\phi) \tan \tfrac{1}{2} M \text{ nearly.}$$

Let M' be an angle such that

$$\tan \tfrac{1}{2} v = \tan\ (45° + \tfrac{1}{2}\phi) \tan \tfrac{1}{2} u$$
$$= \tan^2 (45° + \tfrac{1}{2}\phi) \tan [\tfrac{1}{2} M + \tfrac{1}{2}(M' - M)].$$

Then the Table contains $\tfrac{1}{2}(M' - M)$ for any value of ϕ up to 20°, the arguments being $\tfrac{1}{2} M$ and $\tfrac{1}{2}\phi$.

As an example of the use of this Table, suppose the excentric anomaly of Juno is required for the time to which the elements of the planet are reduced in the Appendix to the *Nautical Almanac* for 1881. The mean anomaly $(= \epsilon - \pi) = 168° \ 39'·43$ and $\tfrac{1}{2}\phi = 7° \ 23'·22$, then

$\tfrac{1}{2} M$	84° 19′·72	
$\tfrac{1}{2}(M' - M)$	— 11·42	from the Table.
$\tfrac{1}{2} M'$	84 8·30	
$\tan \tfrac{1}{2} M'$	0·98858	
$\tan (45° + \tfrac{1}{2}\phi)$	0·11325	
$\tan \tfrac{1}{2} u$	1·10183	
$\tan \tfrac{1}{2} v$	1·21508	
$\tfrac{1}{2} u$	85° 28′·64	
$\tfrac{1}{2} v$	86 30·74	
u	170 57·28	
v	173 1·48	

Here $\tan \tfrac{1}{2} v$ is obtained by adding together the two previous lines, so that there is no subtraction in the operation.

Mr. Godward's Table was printed by the *Nautical Almanac* Office in 1866. It is applicable to all the satellite-orbits showing excentricity, as *Hyperion*, where $\phi = 7° \ 11'$.

THE MINOR PLANETS.—From No. 100 of the *Circular zum Berliner astronomischen Jahrbuch* it appears that the small planet at first announced as No. 190 is proved by Herr Leppig's calculation of its orbit to be identical with No. 94 (*Aurora*); the succeeding discovery therefore takes its number, and for planets found since the beginning of the summer, the numbers, names, and dates will stand thus:—

No. 188	Menippe,	1878,	June 26
,, 189	Phthia,	,,	Sept. 9
,, 190	Ismene,	,,	Sept. 22
,, 191	Kolga,	,,	Sept. 30

Several members of the group as *Dike*, *Medusa*, and others with better determined orbits remain to be virtually rediscovered, and the most interesting of all, from its long period and near approach to the orbit of Jupiter (*Hilda*), was not found at its last opposition. *Atalanta* and *Felicitas* are now nearer the earth than is usual with the minor planets, both being within the mean distance of the earth from the sun; they have the brightness of stars of the tenth magnitude. The following positions are for 12h. M.T. at Berlin, or about 11h. G.M.T.:—

	Atalanta. R.A. h. m. s.	Decl. ° ′	*Felicitas.* R.A. h. m. s.	Decl. ° ′
Nov. 7 ...	1 38 10	+37 50·6	3 11 22	+29 59·1

GEOGRAPHICAL NOTES

We regret to learn that the Earl of Dufferin will be unable to open the session of the Royal Geographical Society on Monday next, as he has received Her Majesty's commands to attend at Balmoral on that day, but it is hoped that he will be able to preside at the meeting on December 9.

PROF. F. V. HAYDEN, in charge of the Geological Survey of the U.S. Territories, has crossed the Rocky Mountain Divide ten times during the past season. He has explored some of the most noted passes, and among them the celebrated Two-ocean Pass, of which he made a careful chart; an account of this we hope soon to be able to give. We hope also to receive from Prof. Hayden an account of the discovery of recent glaciers in the Wind River Mountains of Wyoming Territory, the first known to exist in the United States east of the Pacific Coast. A fine glacier was observed on the east side of Wind River Peak, and two grand ones on the east side of Fremont's Peak. The latter Dr. Hayden named Upper and Lower Fremont Glaciers. Dr. Hayden took great pleasure in traversing much of the same ground passed over by him in 1860, eighteen years and three months before.

A REUTER'S telegram states that Gen. Severtsoff, the explorer of the Pamir plateau, has returned to St. Petersburg, having visited the unknown districts of Lake Rang-Kul and the Sariz Pamir and Alitchur Pamir plateaux. He reports having found a continuous valley extending from Lake Kara-Kul to the Aksu River. Gen. Sjevertsoff has considerably altered the map of these regions and thrown much light on the geography of the Pamir plateau.

WE are sorry to state that no news from the *Florence* has reached Washington from September 13, the date of the last telegram which Capt. Tyson sent to New York when leaving St. John's, Newfoundland. It is feared that the ship was sunk by the recent heavy gales which raged in this part of the Northern Atlantic a few days after its setting out.

THE London Missionary Society have received intelligence of the arrival of their Tanganyika expedition at Urambo, in Unyamwesi, on July 27; they were to leave that place early in August, and hoped to reach Ujiji by the beginning of September. Mr. Hore in his letter divides his geographical description of the country between Kirasa, forty-five miles east of Mpwapwa, and the capital of Unyamwesi into four sections, each of which furnishes interesting details respecting the region traversed by the party. From Kirasa in S. lat. 6° 42′ 30″, elevation 2,700 feet, to Mpwapwa, lat. 6° 22′, 3,200 feet, they were still in the coast region, the country gradually rising to Mpwapwa along an inclosed plain. As it is approached, the mountains of that range bound the view westward, forming the distinct boundary-line of the maritime region. The waters of the Limbo and of the Mpwapwa stream appear to be mere tricklings left by an immense and irregular flow of water during the rains, which, Mr. Hore suspects, will alter the whole face of the country and reconcile the conflicting accounts we have had about the Gombo Lake. The Chunyo Pass is the back door of the maritime region; a slight descent leads to the plain of the Marenga Mhali, which extends through Ugogo, unless the break of elevated forest and ridge between Kididimo and Nyambwa may be said to divide it into two portions. Assuming this, the first portion, consisting of the Marenga Mhali and Eastern Ugogo, exhibits a similar character throughout, that is, a gently undulating plain, with harsh, thorny, scrubby vegetation and small trees, its monotony broken by small irregular and rugged granite hills. A slightly elevated ridge, with a really beautiful forest, divides the first from the second section of the journey. Descending from the first ridge, the party entered the second section, a flat plain, crusted with a salt deposit, in which tall palm-trees form a new feature. At Mizanga the second section terminated abruptly at a precipitous wall 800 feet high. This wall, or "step," extends north and south, but north of Mizanga it trends away to north-west and west-north-west, which bend the expedition followed, and mounted into the third section or stage of the journey a little beyond Makondoku, the westernmost town of Ugogo. This third section was the vast and elevated forest plateau of Uyanzi and Unyamwesi, extending almost unbroken to nearly the meridian of Unyanyembe. The party here found a comparatively bracing atmosphere, and also reached their highest elevation, 4,400 feet, in the meridian of Jewe-la-Singa. At Uyui (lat. 4° 53′, altitude, 3924 feet) the fourth section was entered, the hills and dales of Unyamwesi, and the country maintained the same character as far as Urambo (lat. 4° 37′ 30″, altitude, 3,815 feet), from which place Mr. Hore wrote that the hills, often little elevated ridges, trend generally north and south, and many of their shoulders had to be crossed. This is the region of the Gombe Nullah. "To the passing traveller," Mr. Hore says, "the driftwood and grass in the trees overhead speak to him of some vast inundation rather than of a stream. The Gombe Nullah is the lowest drain of a vast body of water, whose general direction towards the Malagarasi is indicated by it. . . . This fourth stage has brought us on to the water-shed of the Tanganyika."

THE proceedings of the party which last spring went to New Guinea in the *Colonist* from Australia, have hitherto been shrouded in mystery, though rumours have occasionally reached this country as to their want of success. Recently, however, a leading member of the party has been obliged to go to Cooktown, Queensland, through ill-health, and his report of their proceedings has been furnished to the *Brisbane Courier*. Almost all that has previously been heard of them is that they had formed a camp on the Laloki River. Starting north from this point we learn that they proceeded through open country for eight miles, and struck the Goldie River, where they found the first colours of gold. Twelve miles up this river they crossed and proceeded for two miles in a northerly direction, when they recrossed on finding that the river trended to the east. They then took a north-easterly direction for thirteen miles, partly through dense scrub, and reached what they named the Top Camp, thirty-five miles from the Laloki. They made two journeys up the Goldie, one party going a distance of fifty miles, but found no indications of gold. They saw many villages, some numbering 1,000 inhabitants, and all the natives were friendly. Afterwards the party moved further down the river, and camped near the junction of the Mawmika and the Goldie, the former of which flows

into the latter from the east, about five miles north of the Laloki. From this point a portion of the party travelled eastward, between the Mawmika and the Laloki, towards the Astrolabe range, through open forest country, hoping to reach the table-land seen from the spurs of Mount Owen Stanley in their first journey. After about forty miles they met with magnificent waterfalls (about 150 ft.) on the Laloki, and on the fourth day reached the table-land after great labour. They went along it for twenty miles, when their further advance on horseback was stopped by the scrub. Two of the party remained with the horses, while three others, led by three natives carrying provisions, went through the scrub for thirty miles, and struck the head waters of the Goldie. They then proceeded for six miles in each direction, and found, after their great toil, that they had got entirely away from all indications of gold. They returned to the Laloki camp after an absence of thirty-two days, and since then no exploring work has been done. The members of the expedition still maintain that good gold must exist, and they propose to return to Top Camp, and thence to cross a small range to the north-west, from which the gold found in the Goldie River is supposed to have come; from that point they hope to get to another river supposed to run under Mount Owen Stanley, in the direction of Redscar Bay. The total distance traversed by the party during their three prospecting trips was 370 miles, and throughout the whole of that distance not half a grain of gold was discovered.

EARLY in the summer Mr. J. V. Williams was sent to New Caledonia to inspect the nickel mines there on behalf of an English smelting company, and we learn from an Australian contemporary that he thinks most favourably of their prospects. The mines extend from Noumea northwards, along the coast for 120 miles, and the French authorities, disheartened by the inefficient manner in which mining has hitherto been carried on in the island, are said to be prepared to give an English company all reasonable assistance and encouragement.

FROM a Singapore paper we learn that Baron Overbeck and Mr. Alfred Dent, the promoters of the cession of a portion of Northern Borneo to an English company, to which we referred some few months back, arrived at that port at the end of August, after a visit to the lately-ceded territory. They state that matters are quiet there, and that no disturbances are apprehended. A Ceylon planter who went to report upon the adaptability of the soil of the territory for planting purposes, is of opinion that coffee might be cultivated on the west coast, while on the east coast the sugar-cane and other products which usually flourish in the same soil, would thrive well. Altogether the most sanguine expectations appear to exist as to the productiveness of the country.

THE WERDERMANN ELECTRIC LIGHT

WHILE the world is waiting for the announcement of Mr. Edison's method of splitting up the electric light, Mr. Richard Werdermann, a gentleman well known in connection with electric lighting, seems to have solved the problem, to some extent, at least, and he believes that after further experiments he will be able to divide the current into 50, 100, or even 500 lights. Experimental exhibitions of the light have been given with satisfactory results at the works of the British Telegraph Manufactory, Euston Road.

The chief object of Mr. Werdermann is to demonstrate that a number of lights can be placed in one circuit, the current being produced by an electroplating Gramme machine, having an electromotive force of 4 to $4\frac{1}{2}$ Daniell cells. The principle of Mr. Werdermann's invention is that of keeping a small vertical pencil of carbon in contact with a large disk of the same material. In some earlier experiments he found that when he increased the sectional area of the one carbon and reduced that of the other, he produced an electric light with the carbons in actual contact, a small arc appearing at the point of contact. The small carbon is a pencil 3 mm. in diameter; the upper or negative carbon is a disk of 2 inches diameter and an inch thick. The upper carbon is not consumed, so that the waste takes place only in the lower.

In his lamp he places the disk uppermost with the pencil vertically beneath it, sliding up a metal tube which acts as a guide and contact. The pencil is kept in contact with the disk by means of chains attached to its lower extremity passing over pulleys and down again to a counterweight of about $1\frac{1}{2}$ lb. About $\frac{3}{4}$ in. of the lower carbon appears above the tube, and is rendered incandescent by the passage of the current between it and the disk. This pencil is pointed, and retains this point all the time of burning. It is between this point and the disk that the small electric arc appears which gives the greater part of the light.

At the exhibitions which have been given only ten lights were in circuit at once, Mr. Werdermann having no more lamps at hand. The lights were put in what is called the parallel circuit, that is, they all branched off from one wire of the machine and met again on the other. The lamps were estimated to give a light of forty candles each, and the results obtained were most satisfactory, all the lights burning equally well, giving a beautiful white light, which was perfectly steady. By this system of lighting a large number of lamps could be lighted simultaneously, could be put out, and again re-lit. If one lamp should be extinguished it does not affect the others, except by making them burn slightly brighter; but this effect will be obviated by a switch arrangement for regulating the current of the extinguished lamp. The current produced by the machine being very low in tension, the insulation of the conducting cables could be cheaply and easily maintained.

We may state that two larger lamps were shown of 360 candles each. The effect of the light is not dazzling to the eyes, and it was shown naked; in actual practice a common glass globe, as in the ordinary gas lamps, will be a sufficient protection.

NOTES

WE are requested to state that on the occasion of Prof. Wurtz's Faraday lecture at the Royal Institution on Tuesday next, the visitors' tickets issued by the Chemical Society entitle ladies as well as gentlemen to admittance.

SOME of our readers may be aware that Mr. Alfred Russel Wallace is a candidate for the post of Verderer of Epping Forest. We are sure no one can be better fitted than Mr. Wallace to perform the duties attaching to such an office, and as, so far as we know, no more suitable candidate has appeared, the duty of those who have the filling-up of the appointment is plain.

IT is with regret we announce the death of Mr. Charles R. Thatcher, the well-known conchological collector. It will be remembered that we alluded a few months ago to the number of genera and species of shells lately described, due to the indefatigability of this gentleman, including the unique and wonderful *Thatcheria mirabilis*, described in the *Proceedings* of the Zoological Society by Mr. G. F. Angas, and the *Delphinulopsis Lesourdi*, described by Mr. Bryce-Wright in the *Journal de Conchyliologie*, Paris. Mr. Thatcher started, a few months ago, on a five years' collecting tour, and had made the most perfect arrangements for deep-sea and shallow dredgings. He was attacked suddenly by fever, and died a few days after his arrival at Shanghai. There is no greater loss to conchological science than this gentleman's death, as he was undoubtedly the most successful collector of the day.

PROF. F. V. HAYDEN has recently been elected honorary member of the Société Vaudoise des Sciences Naturelles, Lausanne, Switzerland; Société Malacologique, Brussels, Belgium; and the Geographical Society of Halle, Prussia.

IT is announced that the Sheffield meeting of the British Association will begin, not on August 6, but August 20, 1879.

FROM a Government Minute we have received from Mauritius, we learn that the governor, Sir Arthur Phayre, laid before the council of July 20 an application from the President of the Meteorological Society of Mauritius for a grant of money, in order that the results of the meteorological observations made during many years by Dr. Meldrum, the Government observer, may be published in a form which will be advantageous to science and to navigation, as well as to commerce. The form which it is proposed the publication shall take is twofold, namely: synoptic weather charts for the Indian Ocean, extending over twelve consecutive months, and a storm atlas of the Indian Ocean, exhibiting the principal results which have been obtained respecting the more marked atmospheric disturbances in the Indian Ocean during the last thirty years. The objects are set forth in detail in a report by Dr. Meldrum, of which a copy is annexed to the Minute. The matter was referred to the Finance Committee, who, we trust, will grant the sum asked for. If they have any regard to the interests of navigation and commerce in the Indian Ocean, there can be no doubt as to their decision.

COMMANDER PERRIER has been making some interesting experiments with the Giffard captive balloon for the purpose of comparing the qualities of the best aneroid barometers selected from the Paris Exhibition. Each French maker who obtained a silver medal sent two instruments, which were sent up five or six times, and compared with a standard Fortin barometer placed at the foot of the cable. It was discovered that very few of these barometers recovered their original readings until after the lapse of a considerable time. Some photographs were taken of Paris at this high altitude, and are most interesting, although the motion of the car has caused some want of distinctness in the parts removed from the centre of station.

SOME interesting objects have recently been brought to light from the lake-dwellings in the lake of Neufchatel, and are now exhibited at the Neufchatel Museum. Amongst them are three particularly worthy of notice: (1) a large and extremely well preserved piece of amber; (2) a golden earring of masterly workmanship, of the bronze age; and (3) a canoe cut out from the trunk of a single oak tree in perfect preservation. Its length is 7 metres, its breadth 55 centimetres at the prow, and 65 centimetres at the stern; its depth is 19 centimetres, its total height from 22 to 24, and the thickness of its sides 6 to 8½ centimetres.

NEWS from Panama states that the volcano Cotopaxi is in a state of violent activity. Its crater is surrounded by ice and snow, but the clouds of ashes and smoke rising from it can be seen even at Guayaquil on the shores of the Pacific.

THE *Daily News* Naples Correspondent under date November 2, telegraphs that after numerous variations the activity of the eruption of Vesuvius appeared to be then at its height. The lava flowed into the same ravine into which it fell during the eruption of 1872. The seismographs denoted an approaching increase in the eruption.

TWO fresh shocks of earthquake are reported from Buir (Rhenish Prussia), of which the first was felt for many miles around. It occurred on October 24, at 12.30 A.M., and the second one on the same date at 3.45 P.M.

A VIOLET-COLOURED meteor, with a reddish train, was seen at Stanislas, Austria, on the evening of the 24th in the Great Bear and moving in a northerly direction. It is described as thrice the size of Jupiter.

IN NATURE (vol. xviii. p. 652) we gave an account of a verification of M. Pervouchine's first result (vol. xviii. p. 104). We have now seen a very short and neat verification not only of Pervouchine's first but also of his second result (vol. xviii. p. 456). The author (Mr. John Bridge, M.A.) uses the scale whose radix is 16 instead of the binary scale. He assumes r_n to be the remainder arising from the division of 2^{2^n}, then since $2^{2^{n+1}} = (2^{2^n})^2$, it follows that r_{n+1} is the remainder arising from the division of $(r_n)^2$. Hence the remainders can be successfully calculated. Thus for the first result the divisor is (in scale 16) 1(12)001

$$\therefore r_5 = -5249,\ r_6 = +9(11)4,\ r_7 = -59(10)6,$$
$$r_8 = +(12)5(11)4,\ r_9 = -10(10)(15),\ r_{10} = +1702,$$
$$r_{11} = +(13)(10)(13)6,\ r_{12} = -1.$$

Hence $2^{2^{12}}$ has remainder -1, and therefore $2^{2^{12}}+1$ is divisible $7 \times 2^{14}+1$. The second result is obtained in the same manner, the divisor being $(10)(16)^6+1$, *i.e.*, (10)000001, and the last remainder r_{23}. These verifications have been presented to the London Mathematical Society by the author.

A SUPPLEMENT to No. 37 of the *Boletin de la Institucion libre de Enseñanza* consists of a prospectus giving an account of its aims and of its statutes, which we sketched out in a former notice of the Institution. It also contains a list of officers (among the four honorary professors we notice the names of John Tyndall, de Lóndres, and Charles Darwin, de Lóndres) and of the courses of lectures for the students. We have received, also, a copy of the Vice-Rector's (Montero Rios) address, "Las Elecciones Pontificiales." Among other papers read at the *con. erencias* we note "El Aqua y sus Transformaciones," por D. Francisco Quiroga; "Relaciones entre la Sciencia y el Arte," por D. Federico Rubio; "Teorias Modernas sobre los Funciones Cerebrales," por D. Luis Simano; "La Vida de los Astros," por D. A. G. de Linares. No. 33 has papers on "La Geometria Sintética" (continuation); "Los Principales Publicaciones sobre Plantas Insectivoras" (two by Mr. F. Darwin are noticed), and the catalogue of the "Coleccion de Rocas" in the Natural History Cabinet is proceeded with.

THERE has been opened at Berlin the Telegraphic Museum established by M. Stephan, the General Director of Postal Telegraphs in Germany. The exhibition has been located in two large rooms of the General Post Office at Berlin. This is not the first institution of the kind, a telegraphic museum, and even laboratory, having been established at Tokio by the Japannese Government for the use of the pupils in telegraphic engineering. A number of interesting experiments have been already made in that laboratory under the guidance of Messrs. Ayrton and Perry.

WE have received the *Transactions* of the Norfolk and Norwich Naturalists' Society for 1877-8. The society is now in its tenth year, and is both financially and numerically stronger than at any previous period of its existence, the number of members being nearly 190. A glance at the contents of the part shows that the society is fairly carrying them out. We would particularly call attention to the series of letters on the ornithology of Norfolk, by eminent deceased naturalists, edited by Prof. Newton. The society is making it a feature of its work to rescue all such valuable records from loss. The society is also endeavouring to rescue from oblivion the memory of men who did good work in their time, but are fast being forgotten. The complete meteorological report is also an annual contribution; the observations are recorded by the valuable set of instruments, the property of the Norwich Meteorologica Society. Mr. Stevenson's "Ornithological Notes" are also continued from year to year. The last paper is perhaps the most important: it is part viii. of a carefully compiled fauna

and flora of the county. The subjects of the previous parts have been mammals, reptiles, marine, fresh-water, and land shells, fungi, lepidoptera, flowering plants and ferns, diatomaceæ. Other sections will follow as opportunity occurs. We have also received the *Proceedings* of the Norwich Geological Society, part i., which contains some interesting papers, a creditable Fourth Annual Report of the Lisburn School Association, and a satisfactory Report of the Committee of the Goole Scientific Society, which is in its third year.

WE have received the programmes of the arrangements for the session of the various association societies of Cumberland, of the organisation and activity of which we have had already occasion to speak. The programmes seem to us on the whole very satisfactory.

A FINE statue of Corinthian metal resting upon a marble pedestal has just been found through excavations which are being made at the Ponte Sisto at Rome. The statue is 3 metres high and is slightly damaged; the right arm is entirely broken off; yet it is hoped that the damage is not beyond repair. The general belief among archæologists is that the statue represents the Emperor Probus.

AT Berlin a "Society for Ornithology and the Protection of Birds" has just been formed, under the presidency of Dr. Karl Russ. It consists of about fifty members at present, amongst whom there are numerous eminent ornithologists. The special purposes of the new Society are the discussion and practical testing of ornithological questions in regular meetings, the establishment of frequent ornithological exhibitions on as large a scale as possible, and the delivery of public lectures on the science of birds in all its branches.

M. NICOLLE, the organiser of the Exhibition of Maritime and River Industries, which took place at the Palais de l'Industrie, Champs Elysées, in 1876, has received from the French Government, authority to use the same building in 1879 for an exhibition of science applied to industry. M. Nicolle is now busy making his arrangements for next spring. We understand that a very large place will be devoted to the wonders of electricity. This exhibition is opened to all nations, and scientific exhibitors at the Champ de Mars and the Trocadéro will receive circulars giving details before the close of the exhibition. A sum of 700,000 francs has been voted out of the National subscription for covering the travelling expenses of 5,000 working men to the exhibition. A sum of from 4*l*. to 6*l*., according to distance, has been handed over to each of the chosen delegates, and the railway companies have agreed to take only half of the ordinary fares.

FROM America we have received from the twenty-first to the twenty-eighth annual reports of the New York State Museum of Natural History, edited by the regents of the University of the State of New York. Their contents are of the highest interest, comprising many geological, botanical, and zoological communications of value. Amongst others we note an elaborate paper (with map) on the Niagara and Lower Helderberg groups, their relations and geographical distribution, by Dr. James Hall, the director of the museum; numerous entomological contributions by J. A. Lintner; an account of an ascent of Mount Steward and its barometrical measurement, by Verplanck Colvin; remarks on some peculiar impressions in sandstone of the Chemung group, New York, by Dr. Hall and R. P. Whitfield; notes and observations on the Cohoes Mastodon, by Dr. J. Hall. Each part contains a number of well-executed plates. We may, at a future date, return to some of the contents at greater length. We have also before us the *Transactions* of the Academy of Science of St. Louis (vol. iii. No. 4); the principal contents are a valuable treatise by Prof. G. Seyffarth, entitled "Corrections of the present Theory of the Moon's Motions according to the Classic Eclipses;" a note on the larval characters and habits of the blister beetles, by Charles T. Riley; a synopsis of American firs, by Dr. George Engelmann, and other botanical communications by the same gentleman. Also the following publications of interest for entomologists:—Collecting Butterflies and Moths, by Montagu Browne; Preliminary Studies on the North American Pyralidæ, by A. R. Grote; Butterflies and Moths of North America, by Herman Strecker; Lepidoptera, Rhopaloceres, and Heteroceres, by the same (Nos. 14 and 15).

M. W. DE FONVIELLE writes us that Capt. Howgate has not forgotten the suggestion made by him of utilising for ballooning purposes the magnificent coal seam discovered by our Arctic Expedition on the shores of Lady Franklin Bay. Capt. Howgate has made use of the delays arising from the slowness of Congress in granting the required credit for his Arctic colony, in having experiments made to ascertain whether it is possible to inflate balloons without recurring to the ponderous process of preparing ordinary lighting gas. From a report on the experiments which have been made by Prof. Samuel King in the inflation of the "King Carnival," we learn that great success has been met with. The inflation, we are told, was accomplished successfully throughout in seven hours' time. Gas for the purpose was supplied by what may be termed a five-foot generator of the Lowe pattern or build, which employs the modern method of a steam in conjunction with an air blast. Five charges or turns were required to fill the balloon. The amount of gas produced by each charge or turn approximated 6,000 cubic feet. As will be inferred from the two last statements, the capacity of the balloon is about 30,000 cubic feet. The generator employed could have filled the balloon in less than six hours, and would have done so had not the operations been purposely delayed, which delay was occasioned by a state of weather somewhat unfavourable to the ascension which it was proposed to make. The external dimensions of the generator are, height eleven feet, diameter five feet. It is cylindrical in shape, and has an inside fire-brick lining of about six or seven inches thickness, thus leaving a clear diameter for generating purposes of less than four feet. About ten inches of the height is also taken up by the bottom lining. The gas for the inflation was made from anthracite coal. Steam is passed through the incandescent coal. There comes from the generator an impure hydrogen gas containing carbonic acid and oxide of carbon. The carbonic acid is then removed by a suitable and familiar process, and the carbonic oxide remains with the gas. About forty-six lbs. buoyancy is obtained to every thousand feet of gas. The cylinder of the generator can be made in sections, of cast-iron, if no fire-bricks are used, and of wrought-iron if fire-bricks are used. The sections can be luted with clay and then bolted together. The results of these interesting experiments will be laid before the Geographical Society of Paris and Minister of War of France. M. De Fonvielle inquires whether it is really hopeless to find a liquid which might absorb the largest quantity of carbonic oxide, and restore to the hydrogen gas its natural buoyancy.

IT is stated that a committee is being formed in Paris with a view to a permanent International Exhibition at the Crystal Palace. French exhibitors are invited to transfer their productions from the Champ de Mars to Sydenham, and thus realise the original idea of the Crystal Palace as a cosmopolitan museum and warehouse.

WE have received from Mr. Clifton Ward two papers by him reprinted separately—"Quartz as it Occurs in the Lake District," and "Notes on Archæological Remains in the Lake District."

WE have on our table the following books:—"A Manual of Anthropometry," by Charles Roberts, F.R.C.S. (J. and A. Churchill); "The Art of Scientific Discovery," by G. Gore,

LL.D., F.R.S. (Longmans); "Dogma, Doubt, and Duty," by Charles Hoare (Aston and Mander); "Leisure-Time Studies, Chiefly Biological," by Andrew Wilson, Ph.D., F.R.P.S.E. (Chatto and Windus); "Medicinal Plants," Parts 32 to 35, by Robert Bentley, F.L.S., and Henry Trimen, M.B., F.L.S. (J. and A. Churchill).

THE additions to the Zoological Society's Gardens during the past week include a Toque Monkey (*Macacus pileatus*) from Ceylon, presented by Mrs. Tranchell; two Macaque Monkeys (*Macacus cynomolgus*) from India, presented by Mr. C. Loveless; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. Henry Hands; a Grison (*Galictis vittata*) from South America, presented by Mr. H. Potier; a Common Hedgehog (*Erinaceus europæus*), European, presented by Mr. Edwin Etty Sass; a Common Boa (*Boa constrictor*) from South America, presented by Mr. D. W. Bell; two South American Snakes (*Zamenis hippocrepis*) from South America, presented by Mr. G. H. Hawtayne; two Small-Scaled Mastigures (*Uromastix microlepis*) from Busreh, presented by Capt. Phillips; a Mesopotamian Fallow Deer (*Dama mesopotamica*) from Mesopotamia, deposited; two Japanese Pheasants (*Phasianus versicolor*) from Japan, a Gold Pheasant (*Thaumalea picta*) from China, a Lineated Pheasant (*Euplocamus lineatus*) from Pegu, two Barred-Tailed Pheasants (*Phasianus reevesi*) from North China, a Siamese Pheasant (*Euplocamus prælatus*) from Siam, two Swinhoe's Pheasants (*Euplocamus swinhoii*) from Formosa, a Bewick's Swan (*Cygnus bewickii*) from North Asia, purchased.

ON THE VERTICAL DISTRIBUTION OF THE LIGHT FROM LIGHTHOUSES PLACED AT HIGH ELEVATIONS ABOVE THE SEA-LEVEL

THE strongest beam of rays proceeding from lighthouse apparatus in high towers is sent to the sea horizon, as being the direction in which the light can be seen at the greatest distance in clear weather.

My late brother, Mr. Alan Stevenson, suggested the dipping of dioptric lights below the normal to a plumb line in his Report of December 10, 1839, to the Commissioners of Northern Lighthouses in the following passage:—"A more serious inconvenience in using catadioptric zones is that in very high towers where some correction of the position of the apparatus becomes necessary so as to direct the rays to the horizon, the means of regulating the zones in a manner similar to that used for the mirrors is inapplicable. The adoption of a high point in the flame for the focus of these zones, however, affords a considerable compensation for this defect, and it might even be entirely obviated by constructing each set of zones of the form suited to the known height of each tower and the required range of each light if such a correction were found to be of sufficient importance to warrant its application."[1]

But though the precaution of dipping the strongest of the light to the sea horizon was followed out by Mr. Alan Stevenson in high towers it was not always attended to, till the year 1860, when Mr. J. F. Campbell, the Secretary of the Royal Commission on Lighthouses, brought the subject prominently forward, and suggested the internal mode of adjustment. Since then the strongest beam has been invariably dipped to the horizon.

It must, however, be remembered that when the weather becomes even in the least degree thick or hazy, not to say foggy, the range of the light is greatly curtailed by atmospheric absorption and refraction; which last produces during fogs irregular diffusion of the light in every plane. So that at high towers where the beam is pointed to a very distant horizon, it is obvious that the strongest light is directed to a part of the sea, where it cannot be seen with certainty unless when the weather is exceptionally clear.

In an interesting paper on what he calls the "*horizontal visual penetrability of the atmosphere*," lately published in the *Journal* of the Scottish Meteorological Society,[2] Mr. A. Cruikshanks, M.A., makes the following remarks as to daylight observations:—"This shortening of the range of view arises from various atmospheric causes. Such obstructions to the horizontal view as low clouds or mists, or falling showers of rain, snow, or hail circumscribe it at once or abruptly from the observer at a distance of from a few yards to many miles off. The other great obstruction to the horizontal range of view is haze, which may or may not co-exist with the other obstructions, and is supposed to consist of minute particles of water, dust, and smoke floating in the air. The haze, unlike the abrupt obstructions to the view, apparently gradually increases with the distance from the observer till objects become invisible at the distance of three or four miles up to seventy, &c., miles."

Mr. Cruikshanks also gives the following table showing the mean results of twenty-one years' observations made at the middle of the day on terrestrial objects such as hills and mountains:—

Under 5 miles. Seen on days.	5 miles but under 10 miles. Seen on days.	10 miles but under 20 miles Seen on days.	20 miles but under 30 miles. Seen on days.	30 miles but under 40 miles. Seen on days.	40 miles but under 50 miles. Seen on days.	50 miles. Seen on days.
19	—	—	—	—	—	—
81	81	—	—	—	—	—
41	41	41	—	—	—	—
49	49	49	49	—	—	—
38	38	38	38	38	—	—
48	48	48	48	48	48	—
90	90	90	90	90	90	90
366	347	266	225	176	138	90

From this table it appears that during the twenty-one years there were 366 days per annum when an object under five miles distance could be seen, and only ninety days when an object fifty miles distant could be seen.

It has lately appeared to me that the strongest beam should be dipped lower than my brother proposed, and as is now everywhere adopted.

The best of the light should certainly be directed to the place where the safety of shipping most requires it. Now it may in most cases be laid down as axiomatic that the peril of any vessel is inversely proportional to her distance from the danger, whether that danger be a lee shore or an insulated rock. Confining ourselves to this one view of the subject, it would follow that the strongest of the light should, in hazy states of the atmosphere, be thrown as near to the shore, or the rock, as would admit of vessels keeping clear of the danger. But such a restriction as this would, if permanent, greatly impair the usefulness of the light by unduly curtailing its range in clear states of the atmosphere; and of course, *cæteris paribus*, the farther off a sailor is warned of his approach to the shore the better and safer. Besides, the loss due to atmospheric absorption increases in a geometric ratio, and as the rays diverge in cones from the apparatus, the power of the light is further decreased in the inverse ratio of the squares of the distances from the shore.

It is of course well known that the sun itself is extinguished by fog, and we cannot expect to compete with that luminary. But seeing there are endless variations in the density of fogs and in the transparency of the air when there is no fog properly so called, it always appeared to me that had we an easy way of doing so, we ought to increase *temporarily* the dip of the light, and thus during haze and fogs to direct the strongest beam to a point much nearer the shore than the sea horizon. At present we direct our strongest light not only in clear weather, when it *can* be seen, but also during fogs, when it cannot possibly be seen, to a *part of the sea where the danger to shipping is in most situations the smallest*, and this is done to the detriment of that region where, even when the weather is hazy, there is at least some chance of the light being visible, and to a part of the sea where the danger to shipping is unquestionably the greatest.

The simplest mode of depressing the light temporarily would be to raise the lamp itself in relation to the focal plane of the lens. But this is, for several reasons, very inexpedient. The proper adjustment of the apparatus to the focus, so as to secure

[1] "On the Application of Catadioptric Zones to Lighthouses," by Alan Stevenson, LL.B. (Edinburgh, 1840.)

[2] *Journal* of the Scottish Meteorological Society, new series, vol. v. p. 97.

its being situate in the section of maximum luminosity of the flame, is a somewhat delicate one, and ought, if possible, not to be disturbed oftener than is necessary for changing the lamp. Moreover, while the raising of the lamp would depress the light which passes through the refracting portion of the apparatus it would have precisely the opposite effect upon the portions which pass through the totally reflecting prisms placed above and below the refracting part, which would then throw the rays upwards to the sky, where they would be useless. But any desired change could be effected by surrounding the flame with prisms spheric on their inner faces, and concentric with the foci of the different parts of the apparatus, so as to depress the rays before they fall upon the main apparatus. Those prisms which subtend the lens would have their thicker ends lowest, and those subtending the reflectors would have their thicker ends uppermost.

The great disadvantage, unless in the case of electric lights, of employing the temporary apparatus which has just been described, arises from the loss of light by divergence, due to the relation subsisting between the radius of the flame and the radii of curvature of the apparatus itself.

But this loss may be prevented by another plan. Outside of the apparatus, and either close to it, or what would be more convenient, close to the glazing of the lantern, movable refractors made of panes of plate glass could be placed during fogs. In ordinary states of the weather, these fog screens, which would be hung by chains passing over pulleys fixed to the top of the lantern, would be close to the inside of the parapet wall of the light-room, and below the apparatus. If these refractors were fitted with counter-weights they could, in the course of a few minutes, be hauled up in front of the apparatus by the hand when the thick weather came on, and pulled down again when it became clear. The panes of plate glass which act as refractors, would be of prismoidal section vertically having their thicker ends placed downwards. The vertical angle of the prisms would in each case depend on the height of the light-room above the sea, and the distance off shore to which the strongest beam of light required to be dipped during fog. But after more fully considering the question, I have come to the conclusion that a great improvement could be effected even without resorting to temporary expedients. From a series of observations made with two kinds of photometer by Messrs. Stevenson, in 1865, on the penetrative power of light from a first order lens and cylindric refractor, it appears that for an angle of 0° 30′ in altitude above the plane of maximum intensity, and for 0° 30′ below that plane, the power of the light does not vary more than at greatest from 4 to 6 per cent., and that if the strongest part be sent to the horizon, about one-half of the whole is sent uselessly to the skies.

		0 40	·97 ,,
		0 50	·96 ,,

Applying these observations, so far as they extend in the vertical plane, to the case of lighthouses elevated much above sea-level, we see that to dip the strongest beam to a point much nearer the shore than the sea horizon, while it would not appreciably affect the visibility there, would even, so far as the observations go, increase the power of the light nearer the shore. Those who have been close to a lighthouse on a hazy night must have noticed the luminous rays passing through the air far above the sea-level, and cases are adduced by Mr. Beazeley of shipwrecks having occurred when the light could not be seen by the sailors, although their vessels were stranded close to the tower. As the lens has the greatest divergence, and is the only agent for giving light near the shore, it only should be dipped so as to throw as few of the rays as possible uselessly on the skies, while the reflecting prisms, which have much less divergence, will remain as at present throwing their rays to the horizon. By this different distribution of the light from the lens and the prisms, although the strongest beams from the lens were dipped 0° 20′ below the horizon, which causes a loss there of 3 per cent. of lens power, yet the loss on the *whole* light coming from both lens and prisms, taken at Mr. Chance's valuation of 70 and 30 respectively, will be reduced to only about 2 per cent., while the sea near the shore will be more powerfully illuminated than at present. It may, however, be fairly questioned whether the strongest beam ought not to be dipped to 0° 30′, as this would still further increase the power near the shore, and would only depreciate the light at the horizon by about 5·8 per cent. It is well to remember that, should the flame, through neglect of the keeper, fall at any time below the standard height, such a defect will operate most injuriously on the light falling near the shore, and not so much on that sent to the horizon. Now there can be no question that in all ordinary cases a vessel with such an offing as twenty miles, which is the sea-range due to 300 feet of elevation, is in a far safer position than if she were within a mile or two of the shore, and hence the propriety of increasing the light near the shore so long as we do not to any appreciable extent reduce it at the horizon.

T. STEVENSON

MEDICAL ENDOWMENTS AT OXFORD

WE have been requested to publish the following details of existing endowments assigned by founders to the study of Medicine and of Human Anatomy and Physiology as bearing on Medicine :—

I. The Regius Professorship of Medicine, as at present constituted, is worth about 500*l.* a year. The items are : (1) from the Queen's exchequer, 35*l.*; (2) as Master of Ewelme Almshouse, 250*l.*; (3) as Aldrichian Professor of Medicine, 126*l.*; (4) examination and graduation fees, 70*l.* to 100*l.*

II. Lord Lichfield's Clinical Professorship, which is not united with the Regius Professorship, is worth 200*l.* a year.

Dr. H. W. Acland holds both the Regius and the Clinical Professorships : no instruction is given by Dr. Acland in either capacity.

III. The Linacre Professorship of Physiology and Anatomy has absorbed the old foundations for the encouragement of human anatomy, namely, the Tomlinsian Prælectorship and the Aldrichian Professorship. It is worth 800*l.* a year, the sum which Merton College pays in place of the original endowment entrusted to it by Thomas Linacre, founder of the College of Physicians, and once a lecturer on medicine in Oxford. The Linacre Professor is engaged in teaching Comparative Anatomy to candidates for the B.A. degree.

IV. A separate Demonstratorship of Anatomy, worth 200*l.* a year, also still exists, and was intended by the commissioners of 1852 to provide for the teaching of human anatomy, as designed by Tomlins and Aldrich. The gentleman who holds this post is Curator of the Museum of Comparative Anatomy and does not teach Human Anatomy.

V. The beautiful old Physic Garden founded by Earl Danby in 1622 is another heirloom of the Medical Faculty of Oxford. The chair of Botany was endowed by Dr. Sherard and the College of Physicians of London elect the professor. By special provision, the clergy are excluded from this professorship, and *preference is to be given to a medical graduate.* The chair is now worth, with later additions, about 400*l.* a year.

VI. Lastly, a very important trust fund is administered by the governing body of Christ Church, the bulk of which was left by Dr. Matthew Lee in 1755 to provide for anatomical teaching in relation to medicine *exclusively*. Dr. Lee's expression of his

intentions is very clear and precise. He assigns, in his will, 100*l*. a year as the salary of a reader in anatomy; 50*l*. for expenses of two bodies and dissection; 30*l*. to a reader in mathematics and physics, and the remainder to be given in annual prizes of 10*l*. to scholars from Westminster School. The trust is now worth 3,400*l*. annually. It is spoken of in the return made by Christ Church to the Commissioners of 1874 as "Dr. Lee's Benefaction for Senior Students in Natural Science." This is not quite accurate: firstly, because Dr. Lee designed the major portion of his benefaction for students in anatomy as bearing on medicine, and not for natural science generally; and, secondly, because Christ Church uses nearly half of Dr. Lee's trust-money to pay classical scholars from Westminster School; whilst the remainder is used to support a most efficient chemical laboratory, and to pay, in part, the salaries of the accomplished chemist, zoologist, and physicist, who are styled "Lee's Readers." No part of Dr. Lee's bequest is now assigned to medical studies, though it should be stated that the present application of Dr. Lee's fund has obtained Parliamentary sanction.

ON THE THERMAL PHENOMENA PRODUCED BY THE PASSAGE OF ELECTRICITY THROUGH RAREFIED GASES[1]

A PORTION of the experiments described in this paper were made before the publication of Wiedemann's experiments on the same subject. The authors state that if they had known of the work of the German physicist they would probably not have undertaken the investigation, but they have continued the experiments and think them worthy of description as the methods employed differ from those of Wiedemann.

The apparatus used consisted of ordinary Geissler tubes, the electrodes being in wide tubes connected by a narrow one. A large Ruhmkorff's coil with a secondary wire 100,000 metres in length was set in action by two large Bunsen cells, and the current was made and broken by a Foucault's interrupter. In order to measure the induced current a reflecting galvanometer was employed, being placed at such a distance from the coil that the effect of the electro-magnet on the needle was very small; this slight deviation was, however, applied as a correction in all the readings. It was first proved that the current induced on completing the primary circuit was incapable of passing through the Geissler tube, for the galvanometer needle was equally deflected whether placed in the secondary circuit or not, indicating that the movement of the needle was due solely to the direct action of the magnet of the coil; on the contrary, when the primary circuit was broken, a considerable deflection of the needle occurred when the galvanometer was in the secondary circuit, and a slight one, but in the opposite direction, when the needle was influenced by the magnetism of the coil alone.

Tubes containing chlorine, carbonic anhydride, and hydrogen, were employed in the experiments, the electrodes being soldered to the wires from the coil by means of Wood's fusible alloy. The narrow part of the tube was placed in a copper cylinder containing water, or preferably mercury, in which a delicate thermometer was immersed, the deflection of the galvanometer was read every thirty seconds, and the thermometer every minute. When the current indicated by the galvanometer was greatest the increase of temperature was most rapid, but the important fact shown by these experiments is that in every case the rise of temperature divided by the deflection is a constant. Unfortunately the different constants are not comparable, as the experiments were not made with the same tube containing the different gases at known pressures, but with different tubes of nearly the same sizes; but the pressures of the gases are not given.

Some experiments were undertaken to determine the heating effects in the neighbourhood of the electrodes. For this purpose the upper end of a Geissler tube containing chlorine was placed in the calorimeter, the latter surrounding the part of the tube containing the platinum wire. When the electrode was negative about eight times more heat was developed than when it was positive. As the quantity of heat produced when the electrode was positive was very small the relation between the deflection of the galvanometer and the rise of temperature was not so regular in the different experiments as in the other case; and when the electrode was negative it was observed that the quantity of heat increased a little more rapidly than the deflection. More accurate results were obtained by immersing the lower end of the tube in the calorimeter; under these circumstances the quantity of heat collected when the electrode was negative was 22·8 times as great as in the experiments in which it was positive, and while the deflection of the galvanometer varied from 100 to 640, the rise of temperature divided by the deflections increased from 100 to 120 only.

It being suspected that the different effects at the two electrodes might be due to a cause similar to the Peltier effect in solid conductors, an attempt was made to discover if the positive electrode is cooled during the passage of the electricity. There appeared to be a very slight diminution of temperature at the commencement of the experiment, but it was soon marked by the conduction of heat from other parts of the tube.

The calorimeter was next placed on the wide part of the Geissler tube, but not surrounding the electrode, which was 16·5 mm. from the calorimeter. In this case, also, a larger quantity of heat was developed near the negative electrode than near the positive, but the ratio was only 4·9. When a portion of the narrow part of the tube was placed in the calorimeter, that near the negative electrode was slightly more heated than the other portion. When a tube containing hydrogen was used similar results were obtained, but the difference between the quantities of heat at the two ends was very much less than in the case of chlorine.

The next series of experiments was made to determine the effect of different diameters of tube. For this purpose a U-tube containing air of the pressure of two mm. was used, one limb of the tube having a sectional area of 36·3 square mm., the other 12·6 square mm., both limbs being surrounded by calorimeters. The quantity of heat developed in the narrow tube was only very slightly greater than in the other, the ratio being about 1·1. By using another tube with the areas of 116·9 square mm. and 4·5 a similar result was found, but in this case the ratio was not greater than 1·2.

NOTES FROM NEW ZEALAND

THE following notes have been sent us from New Zealand by Mr. T. H. Potts, of Ohinitahi:—

Maori Food Feast.—At the great meeting of Kingite natives convened by Tawhaio to meet Sir George Grey and the Hon. Native Minister, amongst other very interesting incidents was the food feast which was held at Hikurangi on May 8.

A procession formed of several hundreds of women, each carrying a neatly woven basket filled with food, proceeded through the village till it arrived opposite to Sir George Grey's tent; at a given signal the baskets were placed on the ground and stacked into a huge heap. The presentation of each article of food was accompanied with an appropriate chant or ngori, with dancing and facial contortions of an extraordinary character, many of the most ancient persons of different hapus taking part in the celebration.

Amongst the various articles of vegetable food in season was offered:—

Pohua.—The root of *Convolvulus sepium*, as flowery as a potato with a slightly bitter taste.

Sowthistle.—*Sonchus oleraceus.* The Hauhaus, when compelled to use cooked sowthistle, found to their surprise they did not lose condition on this spare diet.

Para.—The thick solid scale from the rootstock of the grand fern *Marattia fraxinea.* This edible was pinkish or pale purple when cut, solid, tough, almost tasteless, with a slightly bitter flavour.

Marnaku.—This esculent appeared in thick junks of about a foot in length; it is the mucilaginous pith of the great black tree-fern *Cyathea medullaris.* It was presented ready dressed, was soft, very sweet to the palate.

Roi.—The rhizome or root of the bracken *Pteris aquilina*, var. *esculenta.* It was offered in the uncooked state, in which it is usually kept ready for use.

Tawha.—The prepared berries of a common forest tree *Nesodaphne tawha.*

Hakeke.—The Jew's-ear fungus *Hirneola auricula-Judæ.* It is found in the forests of Pirongia; that which grows on the Karaka is most esteemed.

On Moa Remains, &c.—There has been so warm a controversy as to the probable date of the extinction of the dinornis, that

any reliable fact connected with the remains of the wonderful animals may be of value to the biological student.

On the low hills and flats north-east of the gorge of the Rakaia, from 1854 to 1858, there were quantities of gizzard-stones lying in small heaps on the surface of the ground; for years no one collected them for scientific purposes, but boys or bush-hands sometimes turned over the heaps, and picked out a "few pretty ones" that happened to take their fancy.

In April, 1857, with two friends, I went up the course of the Rakaia, followed the southern stream, then through the country west of Mount Hutt and Mount Somers, returned to the "plains" by the Ashburton or Haketere River; this was then all new country, not taken up. On the southern side of the Ashburton or Haketere River, on the flats above the gorge, a vast number of moa bones lay exposed *on the surface of the soil;* after I had taken up a run there, I used frequently to pick up specimens from amongst these bones and throw them into heaps, with the view of making a selection therefrom at some future time.

It may be worth mentioning that near that spot, at a now well-known place called "Paddle Hill," I found a paddle made of totana (*Podocarpus totana*), with a longer handle and much broader blade than any hoe that I have seen used by natives; it seemed too large for a paddler kneeling or squatting; it had probably been used to propel a moki or raft.

The Pahu.—The Hauhaus at the Hikurangi meeting were called to their place of worship by the beating of the pahu; it is a long, sonorous piece of wood, made (when possible) from an aromatic tree called porokaiwhiria (*Hedycaria dentata*). It is hung from a cross pole supported at either end by a forked stick. The sound may be heard to an extraordinary distance. It is produced from this rough kind of wooden drum being beaten on its edges by several persons furnished with short batons.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE Cambridge Syndicate appointed to consider the higher mathematical studies and examinations of the university have issued a further report in which they state that they have been led by the observations of members of the Senate in the Arts School, and by the results of the voting on the scheme of examination recommended in their report of March 29, to believe that in the opinion of the Senate the examination in Part III. of the Mathematical Tripos should be independent of the preceding parts, and also that the Senate would be averse to any scheme in which it was not provided that all the subjects should be included in the examinations of each year. They have framed regulations in accordance with these principles in substitution for those rejected by the Senate on May 29, under which it is provided that from the results of the examination in Parts I. and II., the candidates shall be arranged in order of merit as Wranglers, Senior Optimes, and Junior Optimes. Only Wranglers are to be admitted to the examination in Part III., and from the result of the examination in that part only, the Moderators and Examiners shall publish in three divisions, each division arranged alphabetically, a list of those examined and approved. Power is given to the Moderators and Examiners to place in the first division any candidate who has shown eminent proficiency in the subjects of any one group in Schedule III. In each of the papers in bookwork in Part III. a limit is to be fixed to the number of questions to which any candidate shall be permitted to send in answers, such limit to be printed at the head of each paper. The subjects in Part III. are grouped in four divisions. Group A consists of differential equations, calculus of variations, higher algebra, higher parts of theory of equations, higher analytical geometry (plane and solid), finite differences, higher definite integrals, elliptic functions, theory of chances, including combination of observations. Group B, Laplace's and allied functions, attractions, higher dynamics, Newton's "Principia," book i. sec. ix.–xi., lunar and planetary theories, figure of the Earth, precession and nutation. Group C, hydrodynamics, including waves and tide, sound, physical optics, vibrations of strings and bars, elastic solids. Group D, expression of functions by series or integrals, involving sines and cosines, thermodynamics, conduction of heat, electricity, magnetism. From the discussion which took place on the subject on November 2, opinion seems to be pretty much divided at Cambridge as to the advisability of the proposed alterations.

A POST-MASTERSHIP at Merton College, Oxford, for Natural Science, has been awarded to Mr. Geo. Howson, a pupil of Giggleswick School.

SCIENTIFIC SERIALS

Memorie della Società degli Spettroscopisti Italiani, April, 1878, contains a table showing the solar spots and faculæ for each day of observation for the months of January, February, and March 1877. A note by Prof. Tacchini on the solar spots of the first three months of 1877, compared with those of the same months in 1878.—An account of the observations of solar prominences made at Palermo during the first three months of the present year.—Drawings of the chromosphere for the months of March, April, May, and June, 1871.

May.—This number contains full accounts of the transit of Mercury of May 6, 1878, as observed at Rome, with notes on the same by Respighi, St. Ferrari, Millosevich, and Tacchini. —Drawings of the chromosphere for June and July 1871.

June.—Tables of solar spots and faculæ for April and May, 1878.—Note on the spots and solar eruptions of April, May, and June, 1878, by Prof. Tacchini.—A long paper on a cause for the appearance of bright lines in the solar spectrum, by Mr. Meldola.

July.—A paper containing tables of the solar prominences observed at Palermo in April, May, and June, 1878, by Prof. Tacchini.—A long paper by Schiaparelli on the observations of the rotation and topography of the planet Mars made at Milan during the opposition of 1877.

August.—Spectroscopic observations of the chromosphere made at Palermo during the months of April, May, and June, 1878. Tables showing the number of protuberances and spots on the sun for each day of observation for the months of August, September, October, November, and December, as seen at Rome, with notes thereon.—Drawings of the chromosphere for the last part of July, 1871, made at Palermo.

Bulletin de l'Académie Royale de Belgique, No. 7, 1878.—It has been affirmed by more than one observer that, during auroræ boreales, the intensity of scintillation of stars has been considerably increased; a singular influence, if real. M. Montigny, testing such statements, observed twice such an increase (on the nights of April 5, 1870, and June 1, 1878). He notes the fact that this increase coincided with a lowering of temperature of the air in the locality. In the one case this fall occurred exactly at the moment of the aurora and observation of the scintillation; in the other case it preceded the aurora, but was more marked the night of it, and a few hours after observation of the increase in question. He considers the increase due to the cooling, which must have affected first the upper regions of the atmosphere through which the stars' rays pass; and this agrees with the fact that the stars furthest above the horizon showed the increase most.—MM. Spring and Durand study some obscure points in the composition of oxygenated compounds of nitrogen. Finding that the products of reaction, with water, of the body formed by action of chlorine on nitrite of silver, are exclusively nitric acid and chlorhydric acid, their surmise was verified that the chlorine is substituted for the silver of the nitrite, atom for atom, forming nitric chloride. Hence the structure of the group NO_2 of nitric acid is inferred to be the same as that of its correspondent nitrous acid, and the rational formulæ of these two substances must be written respectively $HO.N = O$ and $HO.O - N = O$. M. Melsens seeks to refute M. du Moncel's statements about the cost of his system of lightning-conductors, as applied to the Hotel de Ville, in Brussels, and criticises the instructions of the Paris Commission for erecting conductors on public buildings. —Some letters in a controversy between M. du Moncel and MM. Navez on the theory of the telephone, appear in this number.—M. Malaise announces the discovery of Brachiopoda of the genus Lingula in the Cambrian formation of Stavelot.

No. 8.—The digestion of albuminoids in some invertebrates forms the subject of a paper here from Dr. Fredericq. From a combination of his results with those got by Hoppe-Seyler and Plateau, it appears that the mechanism of digestion is the same throughout the animal kingdom, and the transformation of food in invertebrates is effected through substances that have the greatest similarity to the digestive ferments of vertebrates (solubility in water, precipitation by alcohol). Digestion by means of

a peptic ferment is very rare among invertebrates; a ferment similar to thrypsine, on the other hand, is met with among different classes of these animals.—M. Plateau communicates an account of experiments (with the graphic method and poisons of the heart), on the movements and innervation of the central organ of circulation in articulate animals. *Inter alia*, section of the cardiac nerve diminishes the number of pulsations (in vertebrates, it produces acceleration).—M. Renard describes the diabase of Challes, near Stavelot, in the Cambrian system.—Dr. Koninck continues his researches on Belgian minerals; and there are some papers on mathematical subjects.

THE *Bulletin de l'Académie Impériale des Sciences de St. Pétersbourg* (vol. xxv. No. 2) contains the following papers of interest:—On the occurrence of the musculus peroneo tibialis in Quadrumana, by Dr. Wenzel Gruber.—On a control barometer, by H. Wild (with plate).—On the reduction of Kirchhoff's spectral observations to wave-lengths, by Dr. B. Hasselberg.—On the observed ingress of Mercury upon the solar disc, at the transit of 1878, May 6, by O. Struve, of Pulkowa (with plate), —Catalogue of forty-two new red stars, by E. Lindemann.—On the Russian species of the mollusc *Clausilia*, Drap., by Dr. Oskar Boettger.—On the theory of curves of the shortest parameter on curved surfaces, by F. Minding.—On the hexylenes resulting from tertiary hexylalcohols and their polymerisation, by L. Jawein.—On the action of tertiary iodide of butyl upon isobutylene in the presence of metallic oxides, by J. Lermontoff. —On tetramethylethyl and its derivates, and on the chemical composition of pinacone, by D. Pawlow.

The Journal of the Russian Chemical and Physical Societies of St. Petersburg (vol. x. No. 6) contains the following papers of interest:—On tetramethylethylene and the chemical structure of pinacone, by M. D. Pavloff.—On the glucose derived from lactose, by M. Foudakovsky.—On the action of bromide of aluminium in the formation of the bromides of aromatic hydrocarbons, by G. Gustavson.—On the dextrogyrate terpene obtained from Russian terpentine, by F. Flavitzky.—On the chemical structure of terpenes, by the same.—On dibenzoyldinitrodiphenol, by M. Goldstein.—On some new mineral springs in the Caucasus, by E. Wroblewsky.—On the influence of the surrounding medium upon electrodynamical actions, by J. Borgmann.—On the determination of the magnetic function of liquids, by the same.

Verhandlungen der naturforschenden Gesellschaft zu Freiburg i. B. (vol. vii. part 2).—From the part we note the following papers: On organic cyanides and their decomposition, by A. Claus.—Note on wine analysis, by the same.—On the equilibrium of a system of expanded molecules and the theory of elastic after effects, by E. Warburg.—Observations on the torsion oscillations of an iron wire heated to redness, by Dr. Messer.—On the sensitiveness of alum crystals towards minute variations in the concentration of their mother-liquor, by F. Klocke.

SOCIETIES AND ACADEMIES

CAMBRIDGE

Philosophical Society, October 21.—Dr. Pearson read a paper on a series of lunar distances taken by him during the years 1875-77, mostly at Cambridge and at a place not far distant, the longitude and latitude of each spot being accurately known. He said that they entirely bore out the conclusions at which he had arrived some time back from a much smaller number of observations, and which were communicated by him to the Society in a paper read by him, March 13, 1876 (see *Proceedings*, ii. pp. 414-418), viz., that the errors are such as cannot be called errors of observation of any kind, and may probably arise from the solution of the spherical problem on which the result depends not being, as at present given, strictly accurate. It was mentioned that there is much to justify this conclusion; for example, this method of obtaining longitudes is not much resorted to now in practice (from which it may be argued that it is actually found inaccurate). It is not formally adopted in Germany, though it still is retained in the *Nautical Almanac*, and in the corresponding publication, the *Connaissance des Temps*, issued at Paris. Capt. Toynbee, F.R.A.S., in a paper in the *Nautical Magazine* for February, 1850 (of which there is an abstract in the *Monthly Notices* of the R.A.S.), distinctly states that lunars taken east of the moon give always a result thirty or forty seconds different from those taken west, though his mean result he says was entirely satisfactory; and until the early part of this century all East Indian longitudes were in error nearly 3m. to the east, a result which very nearly agrees with the errors resulting from these observations, supposing them to have been deduced from the new moon of five to eight days old, probably the most convenient time at which to take them from the sun. The whole series, it was stated, consists of 250 separate distances, each distance being either a mean of three or two, or else only one observation, there being about an equal number of each class, though there is no reason to think that the last are less trustworthy than the others in any serious degree; the Greenwich mean time for each being established, with the exception of a very few, within certainly ten seconds. Only 200 of these, the number at present thoroughly verified, were discussed on the present occasion. Classing these in groups of about forty, it was found that the first group gave thirty-two results where the measured distance was in defect of the theoretical distance, and thirteen in which it was in excess. Assuming the rule given in p. 417 of the paper referred to to be correct, this result exactly agrees with what might be expected, it being almost always most convenient, especially for a beginner, to take lunars, at any rate from the sun, under such circumstances as will give this result, while the example of India, founded apparently on observations made at Madras, seems to imply this probable facility, and also that they were made on the new moon, these being more easily taken in our hemisphere than those made on the old one. In the four remaining groups the proportions are 26 to 18: 28 to 15: 25 to 17: 17 to 14: giving a total of 128 observations in defect, and 77 in excess. Rejecting three or four certainly questionable results, the greatest errors occurring are 2′ 59″ in defect, and 2′ 48″ in excess. The true mean has not yet been ascertained, but is certainly in each case not far from 1′—1′ 20″; which, on an average, will give the observer an error of about half a degree of longitude, or of twenty to thirty-five miles, advancing from our own latitude to the equator. There are probably not a dozen clear exceptions to the rule suggested in the communication of March, 1876, that if the luminaries are both on the same side of the meridian, the observed distance is always in defect of the true if the moon be nearest to it, and in excess if she is farther distant; while the same rule holds good, but with less certainty, when the two luminaries are on different sides. The only exceptions seem to arise where the one more distant from the meridian has a greater altitude than the other, or is of a considerably higher declination, and when the distances are very great, *i.e.* from 120° to 130°, in which case the measured distance seems generally to be slightly in excess of the true; but, as might naturally be expected, these last distances cannot often be taken in our own climate. It was explained that all the reductions had been made by Borda's formula, stated in the *Philosophical Transactions* for 1797 to have been the first strictly mathematical solution of the problem. But the results vary only by a few seconds of arc from those given by the system adopted in the large folio published in 1772 by Mr. Shepherd, Plumian Professor at Cambridge University under the superintendence of the Commissioners of Longitude, and while Dr. Maskelyne was Astronomer-Royal; or from other methods which it is believed are allied to this. Two examples were also exhibited of distances reduced according to the elaborate method suggested by Bessel in the *Astronomische Nachrichten* of 1832; Bessel's results, however, do not differ to any great extent from those obtained otherwise. It was suggested that the problem is really one of spherical trigonometry, and from the fact that the errors seem to depend on the position of the luminaries towards the meridian, whereas the old methods of solution depend on their altitudes, and also that the different ways suggested for eliminating the error due to the difference between the geocentric and geographical latitude of the place of observation give different results, a hope was expressed that if these two circumstances were thoroughly reconsidered in dealing with the question, means might be found of discovering a farther correction of the observed distance, which would give a really accurate result.

MANCHESTER

Literary and Philosophical Society, October 15.—J. P. Joule, F.R.S., &c., president, in the chair.—Relative brightness of the planets Venus and Mercury, by James Nasmyth, C.E., F.R.A.S., Corresponding Member of the Society. "On many occasions, when observing Mercury and Venus in full daylight,

I have always been impressed with the strikingly inferior brightness of Mercury as compared with Venus; and as such a condition is the very reverse of what might be expected by reason of Mercury being so much nearer to the sun than Venus, I awaited the rare event of a very close conjunction of these two planets that occurred on September 26 and 27 last. With the advantage of a perfectly clear sky I had the two planets before me for several hours, so to speak, side by side in the field of the telescope at the same time, thus affording me a most perfect opportunity for making a comparison of their relative brightness. It is difficult to convey in words an exact impression of the difference in the brightness of such objects, but I may attempt to do so by stating that Venus looked like clean silver, while Mercury looked like lead or zinc. Were I to indicate my impressions by way of number I would say that Venus was fully twice as bright as Mercury. So remarkable an inferiority in the brightness of Mercury, notwithstanding his much greater nearness to the sun, appears to me to indicate the existence of some very special and peculiar condition of his surface in respect to his capability of reflecting light—a condition that may be due to the nature of his envelope, if such exist, or of that of his surface, by which the fervid light of the sun's rays falling on him are in a great measure quenched or absorbed so as to leave but a small residue to be reflected from his surface. If this be so, it appears to me to be reasonable to suppose that the absorption of so much light must result in a vast increase in the heat of the surface of Mercury beyond what would have been the case had Mercury possessed the same surface conditions as Venus. Whether in the progress of spectroscopic investigation we shall ever be enabled to detect some evidence of metallic or other vapours or gases clinging to or closely enveloping the surface of Mercury that might in some respect account for so remarkable an absorption of the sun's light, we must be content to await the acquirement of such evidence if it ever be forthcoming. It appears to me, however, to be well to raise such a question, so that our astronomical spectroscopists may be on the outlook for some evidence of the cause of so very remarkable a defective condition in the light-reflecting power of Mercury to which I have thus endeavoured to direct attention."—On the water of Thirlmere, by Harry Grimshaw, F.C.S., and Clifford Grimshaw.

PARIS

Academy of Sciences, October 28.—M. Fizeau in the chair.—M. De la Gourmerie read a note on the works of the late M. Bienaymé.—The following papers were also read:—On the decomposition of hydracids by metals, by M. Berthelot. The heat of formation of gaseous chlorhydric acid from its elements is surpassed by that of all anhydrous chlorides, even chlorides of lead, copper, mercury, and silver; gold is the only exception among ordinary metals. The inference that all these metals, except gold, must decompose chlorhydric gas with liberation of hydrogen, is confirmed by experiment. Platina and palladium, also, their chlorides having low heats of formation and little stability, did not decompose chlorhydric gas up to 550°.—On Vice-Admiral Cloué's "Pilote de Terre Neuve," by M. Faye.—On the state in which carbonic acid exists in the blood and the tissues, by M. Bert. The escape of carbonic acid during the respiratory act requires a dissociation of the super-carbonised salts of the blood. These salts were saturated with carbonic acid neither in the arterial nor the venous blood, nor in the tissues. The life of the anatomical elements can only be maintained in presence of carbonic acid in the state of combination. When the alkalis are saturated, and this gas appears in excess in the state of simple solution it rapidly causes death.—Influence of the nervous system on the phenomena of absorption, by M. Moreau. He attached to the dorsal fins of fishes that had swimming bladders a small glass balloon, lighter than the water, and in a few hours the volume of the fish had diminished through absorption of a part of the air contained in the bladder. When a piece of metal was substituted for the balloon, the volume of the fish increased. There is thus a sensation of thrust upwards or downwards, and it is under influence of the former that absorption of air in the bladder takes place, probably through a reflex action. —On *decipium*, a new metal of samarskite, by M. Delafontaine. In the samarskite of North Carolina he finds yttria, erbine, terbine, philippine (yellow (PpO), equiv. about 90; characteristic absorption band about 449 in λ), decipine (white (DpO), equiv. about 122, band 416); thorine and oxides of didymium and cerium. The equivalents of the metals in some of these earths are shown to present interesting numerical relations. *Decipium* is so called from *decipiens*, deceiving. The didymium of cerite is probably a mixture of several bodies, by M. Delafontaine. This is based on spectral observations.—Reply to a recent communication by M. Hirn, on a gyroscopic apparatus, by M. Gruey.—Classification of double stars, by M. Flammarion. Of the 11,000 double or multiple stars discovered, he finds there are only 819 that give certain indications of a relative motion of the components. These groups are divided into 731 doubles, 73 triples, 12 quadruples, 2 quintuples, and 1 sextuple, in all 1,745 stars variously associated. Of these couples in motion 558 have been found with orbital systems, and 316 whose components have been connected merely by the chance of celestial perspectives and form optical groups. In the orbital systems there is a preponderance of retrograde motion from north to south by west (Several other facts are given.)—On the integration of the equation (1) $Ay'^2 + Byy' + Cy^2 + Dy' + Ey + F = O$, by M. Alexeeff.—On involution in curves of n degree, by M. Serret.—Remarks on two integrals obtained by Lamé in the analytical theory of heat, by M. Escary.—Reply to an observation of M. Boltzmann, by M. Lévy.—On the magnetisation of tubes of steel, by M. Gaugain. When a system formed of two parts having different coercive forces is subjected to action of a weak current, the part having the least coercive force is always that which takes the strongest magnetisation (whichever its position, tube, or core).—On a telephone call, by M. Perrodon. This consists in connecting a Ruhmkorff coil with the plate of the telephone, so as to get a loud continuous sound.—On the transformation of valerylene into terpilene, by M. Bouchardat.—Artificial reproduction of melanochroïte, by M. Meunier. This is by keeping fragments of galena in dilute aqueous solution of bichromate of potash.—On the elimination of salicylate of soda, and the action of this salt on the heart, by MM. Blanchier and Bochefontaine. It stimulates various secretions, notably the salivary. In man it is at once expelled by the kidneys (appearing in the urine in 20 mm.); in the dog it appears both in the urine and the saliva, also in the bile and pancreatic fluid. The hypersecretion of saliva is due to action of the salicylate on the grey substance of the central nervous system. In strong doses, the salt stops the heart in diastole.—On parthenogenesis in bees, by M. Sanson.

CLEOPATRA'S NEEDLE AND THE WIND PRESSURE

THE statements recently made in the *Times* respecting the stability of Cleopatra's needle and the maximum intensity of the pressure of the wind in this country have awakened much interest, if not anxiety, about the subject. The appearance of the lofty obelisk balanced on so small a base suggests to many the thought of an egg standing on its end, and presents every idea of instability. This idea is much amplified by a very erroneous estimation, we believe, by most persons of the real dimensions of the base; we have heard this estimated at various diameters down to two feet, but in reality it is in no direction less than five. The statement that the stability of the obelisk is sufficient to withstand a wind pressure of 80 or 90 lbs. per square foot having been made, the storm from Liverpool at once broke on it and upset people's minds, if not the monolith. Thus we learn, from the observations taken by Mr. Hartnup, the astronomer at the Liverpool Observatory, that on January 30, 1868, "it began to blow strongly about 9 A.M., and from that time gradually increased in violence until half-past 11 P.M. on the 31st, when there was one gust of wind which registered 51 lbs. on the square foot. From this time the gale rapidly increased till noon next day, blowing with a severity quite unprecedented in this country. The anemometer which has been erected at the Bidston Observatory is made to register up to 60 lbs. on the square foot, the idea being that no gale would reach that degree of violence. Between eleven o'clock and one o'clock, however, the registering pencil was driven far beyond this limit, and Mr. Hartnup calculated that at several periods the pressure could not have been less than from 70 lbs. to 80 lbs. on the square foot. The anemometer was erected in 1851, and the most severe gale registered up to this time was in December, 1863, when there were three gusts which registered 45 lbs. to the square foot." Further details respecting this remarkable hurricane will be found in the *Journal* of the Scottish Meteorological Society, from which we find that at Glasgow, from 1.15 P.M. to 1.30 P.M., twenty-one miles of wind passed the observatory, giving a velocity of eighty-four miles per hour, or corresponding to a pressure of $35\frac{1}{2}$ lbs. to the square foot, while the strongest gusts registered 42 lbs. on the square foot. At Edinburgh the gale was more severe than at the latter place; cabs and horses are said to have been blown over, but there is no record of the pressure or velocity as there was unfortunately no anemometer in working order. Many authorities state that the maximum pressure of the wind does not exceed 55 lbs. to the square foot in this country, and as this is the figure commonly assumed by engineers in the design of large structures, it is of the greatest importance that the trustworthiness of the Bidston anemometers should be ascertained. Pressure anemometers are obviously liable to errors from the varying modulus of elasticity of their springs and the momentum of their moving parts and supports, while Robinson's anemometers may give a maximum velocity due to small eddies, which is much in excess of the true value. Mr. John Dixon in his letter to the *Times* on the subject gives a good illustration of a pressure of 80 lbs. to the square foot by comparing it to the weight on the floor of a densely-crowded room. It has been ascertained by experiment that the weight of a crowd of persons can attain 80 to 120 lbs. per square foot, the latter figure being reached only when the experiment was made with labourers of above the average stature packed as closely as possible, and the former being commonly taken as the maximum load to which the platform of a bridge can be subjected by a dense mixed crowd. Thus Mr. Dixon remarks, "the windows of a building certainly have to bear an equal strain with the walls, and I suppose it would be immaterial to the glass whether it was placed vertically or horizontally. A densely packed crowd hardly weighs 80 lbs. per square foot of the space it stands upon. Reduce therefore the theory to common sense; would any one dream of standing on a floor formed of glazed window sashes?" On the whole we rather think not, even if, to make the case analogous, means were taken to distribute the pressure uniformly, and we are forced to the conclusion that either the Bidston Observatory is a very strongly constructed building with window-sashes and glass of unusual strength, or that the anemometers are untrustworthy.

Leaving now the question of the maximum pressure of the wind to be decided by meteorologists, there remains to be ascertained what that pressure would have to reach on the banks of the Thames to endanger the existence of the obelisk. Mr. Dixon's assurance has probably set the fears of many at rest; he says: "As to its stability there need be no fear—130 lbs. of wind-pressure would not upset it. The columns of the *Times* are not the place to ventilate calculations and figures." We can assure Mr. Dixon that these calculations would be of sufficient interest to the readers of NATURE to find a place in its columns, but in their absence we are obliged to fall back on our own. The widths of the top and bottom of larger face of the obelisk are respectively 64 inches and 95 inches, the height being 60 feet 6 inches exclusive of the pyramidal point, which would be 7 feet high if intact; assuming, then, an additional foot of height for the lower rounded end, the moment about the base of the pressure on the area of the larger face will be 12,931 foot pounds for a wind pressure of 1 lb. on the square foot. The weight of the stone is estimated at 196 tons, whence, on the assumption of perfect rigidity, the ultimate stability would be 196 tons × radius of base (2·5), and the corresponding wind pressure $= \frac{196 \times 2\cdot5 \times 2240}{12,931} = 84\cdot88$ lbs. per square foot. But the material of the obelisk not being perfectly rigid, it will be seen that this ultimate stability could not be reached. The effect of the wind-pressure is to cause a deviation of the line of action of the resultant pressure on the base from its centre with a diminution of the stress on the windward, and an increase of that on the lee-side of the base; if the decrease exceeds the normal pressure due to the weight the joint will tend to open, while if the increase is carried too far it may reach the crushing strength of the material.

Both these effects have to be considered. Now in the design of masonry work of a substantial character it is

the usual engineering practice to so distribute the stresses that no joint tends to open under the most unfavourable conditions, though this condition is doubtless frequently neglected in flimsy structures. In order that this condition should be fulfilled, the resultant of the pressure on the base must not deviate from the centre of gravity of the base by a quantity greater than x' given in the equation $x' = \frac{I}{XS}$, where I is the moment of inertia of the base about the neutral axis or line through its centre of gravity perpendicular to the direction of the deviation of the resultant, S = the area of the base, and X = the greatest distance of a point in the base from the neutral axis on the side of the greatest pressure. In the case of a circular base $x' = \frac{\text{diameter of base}}{8} = {}$·625 feet in the present instance. The wind pressure corresponding to this deviation $= \frac{196 \times {}^{\cdot}625 \times 2240}{12{,}931} = 21{}^{\cdot}22$ lbs. per square foot. When the wind-pressure exceeds this amount there is still the tensile strength of the cement with which the stone is bedded to resist the tendency of the joint to open on the windward side. While the introduction of a layer of cement under the stone doubtless adds to its steadiness under a wind-pressure of 30 or 50 lbs. to the square foot, it would add a very serious element of danger should the pressure ever approach that recorded at the Bidston Observatory, as the cement on the lee side would probably then be subjected to a crushing stress in excess of its strength, and by giving way would cause the column to heel over to some extent; in fact, if there was any probability of that wind-pressure being reached, it would have been safer to have omitted the cement and trusted for the ultimate stability to the far greater resistance to crushing of the granite. It would be impossible, without making assumptions unfounded on experiment, to estimate with any accuracy the value of the additional stability given by the cement in the case of moderate wind-pressures. We have, however, calculated the conditions of equilibrium, neglecting the tensile strength of the cement, as well as the bending of the stone.

On this assumption we find that a wind pressure of 50lbs, per square foot would cause the joint to open on the windward side as far into the base as the centre; the column would thus be standing only on the leeward half of its base, but the stability would not be endangered by this as the maximum pressure on the base at its outer edge would only amount to 40 tons per square foot, which is less than the crushing strength even of the cement. The line of the resultant pressure on the base would be at a distance of 1·472 feet from the centre, if the bending of the column is disregarded. To take into consideration the flexure of the column would involve too long calculations for our present purpose, even if the modulus of elasticity of granite had been determined with sufficient accuracy to make the results of any value, but this we believe has not yet been done. The conclusions we arrive at are as follows:—As long as the foundations remain secure, the obelisk may be frequently subjected to a wind pressure of 21 lbs. per square foot without the slightest tendency to accident; if subjected at long intervals to a pressure of 40 or 50 lbs. to the square foot, it would probably stand for an indefinitely long period until the fatigue of the cement under variations of stress or its natural decay, if that ever takes place, causes its rupture, but under a pressure of this intensity it must be borne in mind that considerable oscillation would take place, and that if the period of the gusts nearly agreed with the time of vibration of the stone it might be overturned; while if a pressure of 80 lbs. per square foot is reached it is very questionable if the survivors among the inhabitants of the neighbourhood will find it *in situ* when they have time to go and look for it.

DRAPER'S SCIENTIFIC MEMOIRS

Scientific Memoirs: being Experimental Contributions to a Knowledge of Radiant Energy. By John William Draper, M.D., LL.D. (London: Sampson, Low, and Co. New York: Harper Brothers, 1878.)

THE scientific world is to be congratulated on the accession to its literature of these memoirs constituting as they do a distinct historical sketch of the works of a physicist who is at once an ardent experimentalist and a careful theorist. As he remarks in his preface, many of his results of experimental investigation on scientific topics have been largely disseminated in European languages, and many of the conclusions they have presented have been admitted into the accepted body of scientific knowledge. The papers in which these results were published have, however, appeared from time to time in various American and English periodicals, but we now have them collected in a form in which they are accessible and convenient for reference.

The four opening memoirs seemingly occupy their position in the volume for the purpose of calling the attention of the reader to the fact that a large portion of the subject that Kirchhoff treated mathematically in a paper which appeared in *Poggendorff's Annalen* in 1860, and which at the time was considered the foundation of spectrum analysis, had already been experimentally proved and published by our author some thirteen years before. The theorist apparently ignored the work of the experimentalist, and the claim of the one to priority in regard to the enunciation of certain fundamental principles of spectrum analysis is now on the best of evidence disputed by the other. The titles of these first four memoirs and their dates of original publication will give an idea of the indictment framed against Kirchhoff which appears in a note appended to the last of them. They are—

I. Examination of the radiations of red-hot bodies. The production of light by heat, published in 1847.

II. Spectrum analysis of flames. Production of light by chemical action, published in 1848.

III. On invisible fixed lines in the sun's spectrum detected by photography, published in 1843.

IV. On the nature of flame, and on the condition of the sun's surface, published in 1858.

Controversy regarding priority of discovery is always distasteful, and the indictment against Kirchhoff is a heavy one, but the offence might have been charged also against those scientific writers who, careless of history, have been accomplices in doing Draper an injustice. But turning to the more agreeable side of the subject of these memoirs we find that Draper fixed the temperature at which solid

bodies emit light with heat to be 977°, and shows experimentally that as the temperature of an incandescent body rises it emits rays of an increasing refrangibility; also that the amplitude of any particular vibration increases with the temperature, and that to every particular wave-length there belongs a particular colour. But even more remarkable are the deductions he makes regarding light and heat, deductions which, though evident *now*, perhaps, in the present state of knowledge, had by no means *then* the appearance of undoubted truths. He boldly asserted that light and heat were effects of radiation and not forces existing in the radiations themselves.

It is, however, with photographic research that the name of Draper is most generally linked; and as his researches in this line commenced in 1837, two years before the announcement of Daguerre's and Fox Talbot's discoveries, his claim to be considered one of the pioneers in photography admits of no contravention. In his memoir on "Studies in the Diffraction Spectrum" we read: "Several years before the commencement of the discovery of photography by Daguerre and Talbot (1839), I had made use of the process for the purpose of ascertaining whether the so-called chemical rays exhibited interference, and in 1837 published the results in the *Journal* of the Franklin Institute, Philadelphia (July, 1837, p. 45). In this, as will be seen by consulting that publication, I was successful." In his memoir of 1843, he describes the mode in which he photographed the spectrum, from the blue to the ultra-violet, and from near C in the red region to a point some distance below the limit of visibility. The apparatus he employed would at the present time be considered, perhaps, somewhat rude, but, as is well known, the roughest appliances in the hands of a true philosopher are sufficient even for delicate experiment. Thus, in photographing his spectrum we find that he worked before the days of collimating lenses, and with a consequent feebleness of light which was a serious matter when the slow (as compared with that now extant) process of Daguerre was employed for registering the impressions of the radiations. Half an hour's exposure was not too long to give to obtain a developable image, whereas now as many seconds as he gave minutes, with the same size of spectrum and width of slit, would be more than ample. The method by which Draper registered the lines in the red and ultra-red regions is fully treated of in his fifth memoir. The plate received a preliminary exposure to white light, and was then exposed to spectrum; or feeble daylight was allowed access to the plate whilst being similarly exposed; the result, on development by mercury, being that the dark lines in these regions were registered as light lines on a dark background, instead of as dark lines on a white background. This action Draper, Claudet, and others ascribed to the antagonism of the blue and red rays which are found in white light, and heads his memoir "Interference of radiations" in consequence. Till last year this view of the antagonism of rays was accepted as existent, when it received a blow, and probably a final one, from the announcement of the experimental proof that this action was produced through the spectrum possessing the power of accelerating the oxidation of the compound of silver which had been altered by light, and which, when so changed became undevelopable. Whatever may be the explanation of this phenomenon, we have in Draper's photographs of the least refrangible region a gigantic feat, considering the date at which it was performed. Though recent methods may outstrip the more antiquated one as regards rapidity of execution, yet it is due to him to acknowledge that he has long priority in showing that chemical action was not confined to the least refrangible end of the spectrum. As regards the application of photography to portraiture, to our author seems to belong the honour of having taken the first portrait by the Daguerreotype process, and the arrangements adopted for the purpose read rather comically in these days of quasi-instantaneous pictures. In his memoir, "On Taking of Portraits by Photography," he says:—"On a bright day, and with a sensitive plate, portraits can be obtained in the course of five or seven minutes in the diffused daylight. . . . Difficult parts of the dress . . . require intervals (exposure) differing considerably, to be fairly copied, the white parts of a costume passing on to solarisation before the yellow or black parts have made any decisive representation. We have therefore to make use of temporary expedients. A person dressed in a black coat and open waistcoat of the same colour must put on a temporary front of a drab or flesh colour, or, by the time that his face and the dark shadows of woollen clothing are evolved, his shirt will be blue, or even black, with a white halo around it." We are sure that the author cannot have regretted the supercession of a process which entailed such "dodging" to render a portrait practicable, more particularly at the time when he sat for the photograph from which the admirable portrait forming the frontispiece was engraved.

To this same memoir we have also an append in which it is shown that Dr. Draper had priority in taking a photograph of the moon; and when it is considered that the exposure was twenty minutes, and the diameter of the image about one inch, it would not be surprising had it lacked in detail. By an extract from the minutes of the New York Lyceum of Natural History we learn that in this photograph we have "a distinct representation of the moon's surface."

To yet another discovery of Draper's we must refer, since, like some others of his, it has been re-discovered quite recently. He says, in his description of the Daguerreotype process, "On these principles" (he alludes to the different photographic effects produced by different rays of light) "it is plain that an achromatic object-glass is by no means essential for the production of fine photographs; for if the plate be withdrawn at a certain period when the rays that have a maximum energy have just completed their action, those that are more dispersed but of slower effect will not have had time to leave any stain. We work, in fact, with a temporary monochromatic light." With a cigar-box as camera and a spectacle-lens as an objective he tested his theory, and found that on this principle he could photograph an engraving, with all its finest details present. The similarity between Janssen's use of an uncorrected lens for solar work and this is apparent.

Mixed up with photography is actinometry, and here we find that Draper not only invented the chlor-hydrogen photometer, which depends on the combination of chlo-

rine and hydrogen when acted upon by radiations, but that he also used it practically, though not with such nicety of method as subsequently employed by Bunsen and Roscoe. He also invented the ferric oxalate photometer, dependent on the reduction of this ferric compound to the ferrous state and the liberation of carbonic acid. In both of the foregoing we have a measure of the *quantity* of the radiations which these mixed gases, or solution, select. On this particular subject of selective absorption, when chemical action takes place, Draper experimented most fully. He showed, for instance, that the sensitiveness of the surface of a Daguerreotype plate is at its maximum when of a yellow tint, owing to the absorption of the blue rays, and conclusively shows that when it is of a blue tint that these same rays are largely reflected. In fact, he announced, with all the authority of a successful experimentalist, that for the production of chemical action in a compound by any particular ray, the absorption of that ray by the compound was an absolute necessity. In late years we have had several rediscoveries of this important truth, and probably it will be rediscovered again and again, notwithstanding the publication of these memoirs.

We have not space to do more than to mention the memoirs on the "Distribution of Heat in the Spectrum," on "The Chemical Force in the Spectrum" (both titles of which, by the by, are inexact, as Draper himself was the first to prove), and on "The Supposed Magnetic Effects Produced by the Violet Rays," all of which are important contributions to science, as are also those on "The Cause of the Flow of Sap in Plants, and the Circulation of the Blood in Animals," and "On the Decomposition of Carbonic Acid Gas by Plants in the Prismatic Spectrum." All these have been treated in a masterly manner, and the results lucidly and tritely recorded. Reading these memoirs leads us to the conclusion that we have in Draper a successful experimenter, who has been perhaps too little appreciated in the world owing to his too great modesty in neglecting to call attention to the facts he has observed, and to claim for himself honour where the honour was due. Like other men of mark in science, the ardent pursuit of it was undertaken through what might be termed an accident. He tells us in his preface that happening to see a glass containing some camphor, portions of which had been caused to condense in very beautiful crystals, he was induced to read everything he could obtain respecting the chemical and mechanical influence of light, adhesion, and capillary attraction; the experiments he made in connection with these subjects being contained in the volume before us. His thoughts being thus directed to physiological studies, he published papers on these topics in the *American Journal of Medical Sciences*, which created such a favourable impression that he was appointed, in 1836, Professor of Chemistry and Physiology in Hampden Sidney College, Virginia. He afterwards was appointed to a similar chair at New York University, which, we believe, he at present holds.

It would be travelling out of our province to do more than call attention to Dr. Draper as the author of "A Treatise on Human Physiology," "The History of the Intellectual Development of Europe," "The History of the American Civil War," and of "The History of the Conflict of Religion and Science," works which have met with well-merited success, and which show the varied bent of his mind.

The history of the Rumford medal fund held in trust by the Royal Society, and the awards made by this body are too well known to need repetition; but it is not equally well known that a similar medal fund was founded in the United States by Rumford, and is held in trust by the American Academy of Arts and Sciences. The medals were to be awarded for "the most important discovery or improvement relating to light and heat that had been made during the preceding two years in any part of America." The awards of the American Rumford medals have been made few and far between, and till 1876 may be said to have been given for inventions rather than discoveries. At this date the medal was awarded to Dr. Draper (as the medal itself records) "for researches on radiant energy." Had he been an European there can be little doubt but that he would have received one of our English medals years ago, and that his name would have been in the same list with those of Leslie, Fox Talbot, Fresnel, and Faraday. As it is he has the honour of being the first recipient of the American Rumford medal which has ever been awarded for pure scientific research.

A CATECHISM OF BOTANY

A First Catechism of Botany. By John Gibbs, of the Essex and Chelmsford Museum. (Chelmsford: Edmund Durrant and Co. London: Simpkin, Marshall, and Co.)

THIS little book is in its way quite a curiosity. It is a survival of a method of instruction which was very popular in its day, but which it is to be hoped—notwithstanding that Magnall's "Questions" is still said to be a good property—even in country towns like Chelmsford, is on the road to extinction. Catechisms originated in the necessity of giving some uniformity and precision to oral religious instruction. Their great merit is of course that they remove all responsibility from the teacher, and merely require that their formulæ should be taught with patience and perseverance. They render unnecessary, indeed even undesirable, any knowledge of the subject on the part of the teacher, and hence it is easy to see the reason of their popularity amongst persons engaged in education, and who, possessed of no scientific training, are yet anxious to get credit for teaching scientific subjects. Mr. Gibbs has evidently felt some uneasiness on this head, and points out accordingly in his preface that:—

"The answer to every question may be verified by examination of the plant itself in all its parts to which reference is made. Only in such a way can this catechism be made useful, and by such criticism its value will be ascertained."

But the insidious influence of the purely dogmatic method makes itself but too evident in the next sentence, which is surely the strangest ground of recommendation ever urged for a scientific book:—

"In its original form it was admitted to the International Exhibition of 1871, which contained nothing but what the Committee of Selection approved as excellent."

The approval of the Committee must have been easily given if it extended to the following curious inquiry :—

"83. *In the common horse-tail of our ditches every internode of the stem seems to consist of two hollow tubes, one inside the other. How do these differ from the wood and bark of plants more highly organised?*"

Another extract will show the catechetical method in its most aggravated form. Imagine the children in some small country school bitterly endeavouring to commit to heart the following :—

"261. *Can you describe the flower of the fuchsia?*

"It is that of a Calycifloral Exogen, with a coloured calyx valvate in æstivation, and consisting of four sepals. The corolla is twisted, and consists of four petals. The stamens are eight, in two rows, with long filaments. The pistil is syncarpous, with an inferior ovary, a long style, and a stigma of four lobes."

It is fair, however, to say that some of the information imparted by Mr. Gibbs is less indigestible. If the whole catechism were as sensible as the following, it might be actually useful :—

"221. *What name do botanists give the cabbage?*

"*Brassica oleracea.*

"222. *What do they call the cauliflower?*

"It is a variety of the same species.

"223. *Is not the difference between them enough to make them appear distinct species?*

"It would be if they were not known to be derived from a common origin.

"224. *Then how came they to differ so much?*

"They differ in consequence of cultivation having increased the luxuriance of their growth; some plants producing an abundance of large and succulent leaves, and others an extraordinary number of flower buds. Such plants have been selected by gardeners for many generations, till they have resulted in the production of distinct varieties.

"225. *How are these varieties perpetuated?*

"The varieties of *Brassica oleracea* are perpetuated by seed which is taken from plants kept carefully apart from other varieties of the same species, for if the pollen of one variety happen to fall on the stigma of another, the seed produced by that flower would give origin to plants intermediate or uncertain in their character. Sometimes new varieties appear in this way."

But the catechetical method in its unrelieved dryness is too much even for the author. He preserves his gravity with undeviating firmness till we come to the last question and its answer, which deserve reproduction in the pages of NATURE as something absolutely unique in botanical literature.

"322. *Describe a Daisy.*

"Of this little plant of the Composite order,
Bellis perennis is surely the name ;
A perennial herb in the garden's gay border,
To ornament which from the meadows it came.

"Its roots of a good many fibres are growing
From under the sides of a prostrate rhizome ;
Which branches above, but is never found going
At any great length from the centre to roam.

"Spathulate leaves in a rosulate cluster,
Every ramification surround ;
And in the middle about which they muster,
A simple peduncle is commonly found.

"Are these the green leaves of a bud? Let us waken
With knowledge and skill to examine the facts ;
And then shall not be for a calyx mistaken
A real involucre consisting of bracts.

"For each of the ligulate florets composing
The circular ray is a separate bloom ;
And each little cup in the centre reposing,
For every part of a flower has room.

"It seems that the cup of the calyx adhering
Unto an inferior ovary so,
Accounts for that innermost organ appearing
To be in the place where we find it below.

"The corolla above it of tubular figure,
Coherent epigynous petals compose ;
As whoso describes it with technical rigour
By five little teeth on the edge of it knows.

"The stamens are called syngenesious truly,
Because of the fact that their anthers cohere ;
The style passes through them, and on it will duly
A couple of stigmatic branches appear.

"When all this is done and the blooming is over ;
When fruits monospermous are ripen'd and gone ;
They leave the receptacle nothing to cover
Its form which we find in the shape of a cone.

"If now I have done my agreeable duty,
I venture to hope I shall have better luck
Than the flower itself, which, because of its beauty,
Some ruthless examiner haply may pluck."

T. D.

OUR BOOK SHELF

A Manual of Anthropometry. By Charles Roberts, F.R.C.S. (London: J. and A. Churchill, 1878.)

THE full title of this moderately-sized volume gives an accurate account of its contents. It is "a guide to the physical examination and measurement of the human body, containing a systematic table of measurements, an anthropometrical chart or register, and instructions for making measurements on a uniform plan."

The author's appetite for figures is marvellous, and would be commendable, were it not too indiscriminate, his tables having the air of being immense hotch-pot collections, both in their titles and headings and in the run of their results, which is more irregular than is natural to the statistics of generically similar facts. The author does not seem to recognise the importance of what is really the main question to the statist, namely, how to obtain trustworthy results with a minimum of effort. He seems to squander his efforts, the results he obtains being very disproportionate to the labour bestowed in getting them. Thus in a chart, of which the leading idea is very good, for recording measurements at frequent intervals of different parts of the body of the same growing person, he has places for the entry of the measurement of more than sixty parts, a number altogether too great to be dealt with satisfactorily in statistical combination with similar measurements of other persons. The theoretical part of the book is altogether loose and unsatisfactory; it is a mixture of imperfectly understood Quetelet and water; Quetelet himself being somewhat lax in theory and much too watery already. On the other hand, the volume has many merits, and it is a pleasant duty to notice them as much as it is a disagreeable one to point out the defects in a work that aspires to set a standard to which future statisticians should conform. Thus the arrangement of the sample statistical tables is very convenient in its main features, and to that extent well worthy of imitation, though not as good as might be in all its details. For instance it omits mention of any measure of variability, such as the Probable Error. The book includes a long and useful list of anthropometric works copied with important additions from the American work of Dr. J. H. Baxter. The author is evidently most zealous, and having himself measured and weighed people by the hundred, he writes with the aplomb due to

much experience. His zeal is contagious, and consequently much of what he has written will favourably attract the attention of the statist.

It is a pity that the custom does not exist of weighing and measuring all the members of a family at frequent intervals between childhood to manhood, seeing how critical a test of sanitary condition is afforded by the progress of growth. Each illness leaves its mark, therefore a chart of height and weight with accompanying remarks, would give in a compendious form a very valuable life-history of the individual.

A Text-book of Arithmetic for Use in Higher Class Schools. By Thomas Muir, M.A., F.R.S.E. (Daldy, Isbister and Co., 1878.)

"NUMBER," infers "Recorde," in his "Whetstone of Witte," "is the onelie thing (almost) that seperateth man from beastes. Hee therefore that shall contempne numbre, he declareth himselfe as brutishe as a beaste, and unworthy to be counted in the fellowshippe of men. But I truste there is no man so foule ouerseene, though manie right smallye do it regarde."—(De Morgan, "English Mathematical and Astronomical Writers.") We have done with the miserable mercantile compendiums founded on Cocker, which De Morgan condemned, and have had, since his own "Arithmetic" appeared, many works of high value. Mr. Muir's work is worthy of taking place with these. His aims are high—mathematical accuracy, rational treatment, the presentment of essentials, with the accessories in due subordination, the production of a work suited both for mental training and as a preparation for the practical business of life. There is perhaps matter given more suitable for the use of teachers than of pupils—that is, for a school book we think much might be more concisely put. Persons taking up the subject at a more advanced age may find this fulness of explanation very valuable. The exercises are good and varied, and there is a chapter containing notices of books for future reading.

In connection with these notices and Mr. Muir's chapter on the roots of numbers (a part of the work which appears to us to require excision and a new treatment), we may add the following title :—"Éléments de Calcul Approximatif." Par Charles Ruchonnet (de Lausanne). Seconde Édition. (Paris, 1874)—a work which we have already noticed in NATURE.

The work is a thoroughly reliable one, accurately and neatly printed.

The Elements of Dynamics (Mechanics), with numerous Examples and Examination Questions. By J. Blaikie, M.A. (Edinburgh: J. Thin, 1878.)

MR. BLAIKIE says "special pains have been taken to establish the necessary propositions by proofs involving no higher mathematics than the geometry of the first two books of Euclid, and algebra as far as simple equations. At the same time the nomenclature, definitions, and general treatment are in harmony with advanced modern works on the subject." The author starts with kinematics and kinetics and derives statics as a particular case. A chapter is devoted to machines and another to hydrostatics. The objects laid down in the above statement have been well kept before the writer's eye, and the result is a good introductory book for young students. A word of decided commendation is due to the selection of general examples; there are besides some six university examination papers, specimens from the old universities, and from Edinburgh, London and Glasgow. The list of errata we have made is a very slight one, and we say this after working out all the examples.

This accuracy and carefulness of selection may be attributed to the fact of the work having been examined by such men as Professors Tait and Balfour Stewart and Mr. N. M. Ferrers. That our favourable opinion of this work is not singular may be inferred from the fact that a second edition is already in preparation.

Handbook to Map of the Geographical Distribution of Animals. By Andrew Wilson, Ph.D., &c. (Edinburgh and London: W. and A. K. Johnston, 1878.)

THIS is a very brief statement of the extent and limits of the six zoological regions and sub-regions, as given in Mr. Wallace's "Geographical Distribution of Animals," with an enumeration of the chief groups of mammals and birds characteristic of each region. The only novelty is that of placing the Ethiopian region fourth in order, thus separating it from the Palæarctic and Oriental, to both of which it is closely allied, and making it follow the Australian, with which it has no affinity. It is difficult to see the reason of this innovation, which will certainly not be considered an improvement. The map is in two large sheets, with the regions and sub-regions copied from Mr. Wallace's map, and similarly distinguished by colours. It is, however, a mere outline, and entirely without names—a great deficiency in any case, and especially when intended for junior students, to whom alone such a meagre sketch of the subject would be acceptable.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Gigantic Land Tortoises

MY attention has been called to the recent discussions in NATURE (vol. xviii. p. 220 *et seq.*) in reference to the geographical distribution of the gigantic land-tortoises of Malta, the Galapagos, and other oceanic islands (see also the annual address of the president of the Geological Society). On my return to America in 1864 from a four-years' residence in the guano key of Sombrero, West Indies, I put a small collection of fossil reptilian remains, found on that key, in the hands of the late Prof. Jeffries Wyman, of Boston, who had kindly consented to examine them. His report on the subject, received in August, 1865, was added as an appendix to a paper of mine on the geology of the key, but the latter was partially injured by a fire in the study of the late Prof. Joseph Henry, of the Smithsonian Institution, and its publication consequently postponed. I have since found time to restore and publish only a portion of my own paper,[1] but the report of Prof. Wyman has remained untouched among the charred MSS. of my observations on the guano-deposit of Sombrero. I inclose herewith a copy of Prof. Wyman's report, and also his subsequent autograph letter, in returning me the specimens. (In the former I have supplied, in italics, the probable words which are missing along the singed edges of some of the leaves.) I have thought these details worthy of statement in justice to this distinguished comparative anatomist —who recognised thirteen years ago the occurrence of this interesting fauna in a locality of the Atlantic, and one evidently unknown to the recent investigators—and in explanation of the long delay in the publication of his views. The specimens in question remain still in my possession, with the exception of one in the museum of this school.

I may further state that fossil specimens of these turtles, mostly fragmentary, have been found in many of the northern excavations upon Sombrero, since they were first worked, in 1856, and perhaps are still, as its exploitation has been continued by an English company for many years past. They occur altogether in the guano-veins which intersect the limestone beds to an unknown depth beneath the sea-level, and which are certainly but insertions from an ancient surface-bed of rock-guano, overlying but long since entirely denuded along with the crown of the key. In 1860–61, just before my arrival, enormous quantities of a guano-breccia were taken out from the largest of

[1] "Ann. Lyc. of Nat. Hist. of N.Y.," 1868, p. 251.

the northern quarries, which was largely made up of these fragments, probably to the amount of hundreds of tons! It will be seen from my paper (*loc. cit.*) that the Sombrero Key is merely the eroded remnant of an atoll, which presented, by its peculiar isolation, the most favourable refuge for this Chelonian family. Their existence in this region seems to furnish an important link in reference to the question of the ancient geographical connection between the Mascarene and the Galapagos Islands. Their occurrence has never been reported on the other guano keys of the Caribbean Sea—Navassa, Swan, Monk's, Redonda, &c; but I would suggest the propriety of an examination of the cargoes of guano from Navassa, &c., as well as from all other localities, which may still be brought to England. The conditions of the existence of this fauna will be discussed with more detail in the remainder of my Sombrero paper, when sufficiently restored and re-written for publication.

ALEXIS A. JULIEN

MY DEAR SIR,—The collection of fossils from the Sombrero Key, which you kindly placed in my hands for examination, comprises the remains of birds, turtles, and Saurian reptiles. Those of the first, and from the more superficial deposit, appear to belong to existing species of sea-birds now found along the coast, and have undergone no change. The following comprises a list of such specimens as are sufficiently well preserved to be identified. There are many other specimens, but they are so much broken that I have not been able to determine them. Specimens numbered from 1 to 17 inclusive are bones of turtles, and those from 1 to 11 inclusive are all from the same, viz., the middle, deposit.[1]

1. Left humerus of a large turtle; the ends are gone and the shaft alone is preserved; it is 6 inches in length, and at the smallest part has a diameter of 2·07 inches, from before backwards, and of 1·57 inches from side to side. Admitting that the usual proportions existed, the whole length would have been about 12 inches.

2. A fragment comprising a large part of a humerus; nearly the whole of the articular facet is preserved, its longest diameter measuring 2·38 inches, thus indicating a large species like that of 1.

3. Middle portion of a femur, 1·25 inch in diameter. This would indicate an entire bone of from 8 to 9 inches in length.

4. Lower third of a left humerus; the inner tuberosity is broken off, and does not therefore exhibit the emargination found in most turtles. This is somewhat smaller than the same part from a Galapagos turtle (*T. elephantopus*), the length of whose carapace was 27 inches.

5. A femur from which the upper portion is broken off. This is of the same size as the corresponding part in the Snapper (*E. serpentina*), the carapace of which was 15 inches long. The transverse diameter of the condyles was 1·35 inch.

6. Middle portion of the shaft of a humerus, 0·55 inch in diameter.

7. A similar fragment, 0·75 inch in diameter.

8. A fragment of one of the marginal bones, 1 inch in thickness. This could have only belonged to a turtle of the size of the Galapagos species.

9. A fragment of the right ilium, including the middle portion, the longest diameter of which last is 1·55 inch, and the two facets for the articulation of the ischium and pubes.

10. The shaft of a femur 0·75 inch in diameter.

11. Upper half of the ascending portion of the scapula; this has a diameter at the articular end of 0·90 inch.

All of the above specimens are from the same deposit in which the matrix is soft and crumbling.

12. Lower two-thirds of a humerus partly imbedded in a very dense matrix, which contrasts very strongly with that found in connection with the preceding specimen. The fragment is 3·50 inches long, 2·35 inches across condyles; a part of the inner one is broken off, but there are some signs of the lateral groove and notch at the end. The narrowest part of the shaft measures 0·92 inch in diameter.

13. Lower end of a radius from the left side.

14. Fragment of a carapace having a raised articular surface for the articulation of the pelvis, as in some of the land turtles.

15, 16, 17. Other fragments of a carapace.

17*a*. An irregular cast of a part of the interior of the carapace and plastron, the walls of the latter (?) being broken, but portions of them still adhering. Three of the median bony dermal plates, the largest 2·25 inches in diameter. These plates have neither ridge nor tuberosity on the median line, though there are slight projections over the head of the ribs resembling those of very old specimens of *E. serpentina*. The plastron is indistinctly seen, but enough remains to show that its union with the carapace was by a broad surface, and not by a narrow one, as in the marine and some of the fresh-water species.

18. A caudal vertebra of a saurian.

19. Anterior half of a lower jaw of a saurian which resembles in size and the arrangement of the teeth that of the *Iguana cornuta*, as figured by Cuvier in the *Ossemens fossiles*. The points of the teeth are compressed and show some signs of having been serrated, though now worn nearly smooth.

20. Fragment of a femur, which closely resembles in size and shape that of the *Iguana tuberculata*.

21. Another fragment of a femur closely resembling the last, but about one-fourth smaller.

The remains of turtles form by far *the largest part* of the collection of which the above is a list. From the fact which you communicated to me, that at *the present time* not a single species of turtle inhabits the *Sombrero Key*, the question at once arises whether these remains belong to species like those now inhabiting the sea, or to such as live either in fresh-water or on the land. After a careful comparison I do not find that any of them can be considered as of marine origin. All the long bones, consisting chiefly of arm and thigh bones, differ in a marked degree from corresponding ones of the sea-turtles in having the axis of the bones strongly curved instead of being nearly straight, in having the shaft at its middle nearly round instead of flattened, and in having the distal ends proportionally much broader. A comparison of the fossil fragments with the corresponding parts of fresh-water and land species is much more difficult, since these two kinds, in their anatomical features, so gradually shade into and so closely resemble each other that there is really no well-marked line of distinction.

It is certain, nevertheless, that the remains above noticed belong either to the fresh-water or land species, and the discovery of them where such no longer exist alive indicates a great revolution in the *previous history* of the island, and is therefore a *marked fact*. In addition we have the interesting remains of one of the species, which is certainly extinct and of gigantic size, equalling the largest specimens which are found living in any part of the world, and thus surpassing any now found in North or South America. The nearest instances of turtles of similar size are in the Galapagos Islands, where is found *T. elephantopus*. Specimens 7 and 10 indicate species as large as those now inhabiting the Americas.

Although among turtles it is almost impossible to establis species from fragments of bones, and these not the most characteristic ones, yet I have no doubt that the remains here described show the existence at least of three species, one, the longest of which represented by specimen 1, was undoubtedly an inhabitant of the land.

JEFFRIES WYMAN

Cambridge, August 14, 1865

The Figure of the Planet Mars

IN the report of the proceedings of the Academy of Sciences at Paris for October 22 (NATURE, vol. xviii. p. 712), with reference to a communication from me relative to the flattening of the planet Mars, it is stated that I confirm M. Amigues' conclusions from independent calculations. Allow me to say that the communication referred to, has clearly established by reference to dates of publication, that the calculations I had been the first to make were confirmed by the subsequent results of M. Amigues. A formula presented by me in February, 1870, in which the mean density, surface density, and velocity of rotation of Mars are expressed in connection with its ellipticity, was reproduced by apparently identical methods by M. Amigues, in the *Comptes Rendus* for June, 1874. The conclusions drawn from this formula by M. Amigues were, that in order to account for the high amount of ellipticity assigned to Mars by many astronomers its mean density must be less than its surface density. My conclusion was, on the contrary, that the high ellipticity alluded to was improbable and that the values given by Bessel, Oudemanns, Johnson, and other astronomers, whereby Mars would have an ellipticity nearly the same as that of the earth, should be adopted until the subject was cleared up by fresh observations.

H. HENNESSY

Royal College of Science for Ireland, November 2

The Colour-Sense

WITH reference to Dr. Pole's valuable papers on Homer's colour-blindness, it may interest your readers to learn that I have now nearly completed a work on "The Origin and Development of the Colour-Sense," which will be shortly published by Messrs. Trübner and Co. In it I have endeavoured to show (*inter alia*) that the use of colour-terms in the Homeric poems is strictly analogous to that of other races, existing or extinct, at the corresponding stage of culture; and that both depend, not upon dichromic vision, but upon a defect of language closely connected with the small number of dyes or artificial pigments known to the various tribes. To establish this result I have sent a number of circular letters to missionaries, Government officials, and other persons having relations with native uncivilised races in all parts of the world; and their answers to my queries, framed so as to distinguish carefully between perception and language, in every case bear out the theory which I had formed. As my results will so soon be published elsewhere, I shall not burden your columns with them at present, but may add that my researches lead me to place the origin of the colour-sense far lower down in the animal scale, as evidenced both by the distinctive hues of flowers and fruits, and by the varied integuments of insects, birds, &c., so far as these are the result of sexual selection, or of mimicry and other protective devices.

GRANT ALLEN

Magnus's "Hydrostatics" and the "London Science Series"

I KNOW it is unusual for an author to offer any reply to the favourable or unfavourable criticism of his reviewer; but I shall be glad if, by way of exception to this wise rule, you will allow me to make a few remarks on the notice of my little book which appeared in NATURE, vol. xviii. p. 693, as they refer to a subject of wider interest than the contents of the work itself. It unfortunately often happens that an author is able to detect that the reviewer has taken no further trouble than to make a few quotations from the preface of the book under review. For my own part I have no complaint on this ground. On the contrary, if the reviewer had even glanced at the preface he would have seen that the book has not been written for the use of very young boys, but that it "is intended for the use of those pupils in the upper Forms of schools who have already acquired some elementary knowledge of the principles of mechanics"—for those, in fact, to whom, after some adverse criticism, he is good enough to say "the book will undoubtedly prove useful."

My object in writing, however, is less to disprove anything that may have been said with regard to my own book than to take away the point of the criticism which has been directed against other volumes of the "London Science Series." As one of the Editors of this Series, I am anxious to correct an erroneous but somewhat prevalent impression that these books are intended to be "science primers." Nothing could be farther from the intentions of the Editors of this Series than the attempt to rival the excellent and original science primers published by Messrs. Macmillan. Judged by such a standard they must necessarily appear difficult and elaborate. But the standard is incorrect. The books of the present series are, as they purpose to be, essentially class-books, and many of them have been expressly written to meet the wants of the pupils of the higher forms of schools.

Although my reviewer "cannot imagine" that I "can be acquainted with science teaching in schools or its requirements," I may lay claim to so much experience as a teacher and school-examiner as shows me that a class-book should be rather above than below the average attainments of the form, and should be so written as to encourage the more advanced pupils to pursue their studies to a higher point.

If Science is to take the place of Classics in any of our schools it should be so taught as to afford an equivalent amount of mental discipline. If this is not the case the modern school will always rank below the grammar school, and there will be some ground for the alleged inferiority of the modern, with respect to the classical side of a public school. To teach science properly several hours a week ought certainly to be given to it, and I should be disposed to criticise somewhat severely the time-table of any school in which the boys "probably have one hour, or at most two, to devote to the subject in a week." Indications of showy and superficial knowledge on the part of boys who take up Science instead of Classics are not wanting, and this showiness may be partly due to the want of thoroughness of some of the text-books commonly in use.

PHILIP MAGNUS

Savile Club, London, November 3

[We have sent Mr. Magnus' letter to our Reviewer, who replies as follows.—ED.]

MR. MAGNUS complains that if his reviewer "had even glanced at the preface he would have seen that the book has not been written for very young boys, but that it is intended for the use of those pupils in the upper Forms of schools who have already acquired some elementary knowledge of the principles of mechanics." To this I may reply, firstly, that I did much more than glance at the preface; secondly, that I nowhere assert that the book is intended for "very young boys;" and thirdly, that I assert my belief that "for advanced boys in Upper Fifth and Sixth Forms the book will undoubtedly prove useful." By "young boys" I meant boys in the Upper Fourths, Removes, and Lower Fifths, whose average ages range between fourteen and sixteen. It is in these Forms that the principal science teaching in a Public school takes place.

I nowhere have asserted that the book is intended to be a "science primer," and my remark that it is intended for "school purposes" is taken from the commencement of the Editor's preface.

I am the more constrained to repeat my belief that the author cannot "be acquainted with science teaching in schools or its requirements" when I read his remarks on the character of a school class-book, and when I notice that he speaks of "science taking the place of classics."

I believe I am right in stating that in no school in England does science take the place of classics. I should sincerely deplore such a result. Any attempt to enforce it could only result in utter failure from an educational point of view. Science can never "afford an equivalent amount of mental discipline" to classics. Mr. Magnus may not be aware of the fact that science is taking the place of Latin verses in our public schools, and that no proposition has ever, as far as I know, been made to the effect that classics should be abandoned.

Finally, Mr. Magnus tells us that he "should be disposed to criticise somewhat severely the time-table of any school in which the boys probably have one hour, or at most two, to devote to the subject in a week." Possibly he would; but the fact is no less true that in almost all our principal schools two hours a week is the maximum time which is given, in the ordinary course of school work, to any one subject of science, and class books must be framed in accordance with such usage.

THE REVIEWER

The Discovery of a Crannog in Ayrshire

IN his letter reporting this interesting discovery (NATURE, p. 695), Dr. Munro remarks that amongst the constituents of the crannog was "brushwood, amongst which beech, birch, and hazel were readily recognised."

Now as *beech* is certainly not at present a *native* of Scotland, and as, to the best of my knowledge, it never has been claimed as an indigenous tree at any period, the finding of beech branches in the Tarbolton crannog is not the least interesting part of the discovery, and I venture to hope that Dr. Munro will be able to give us proofs that the brushwood he mentions is, beyond any doubt, beech.

Of course the other trees—oak, birch, and hazel—are truly indigenous. The *absence* of Scots-fir is also not without interest.

F. BUCHANAN WHITE

The Power of Stupefying Spiders Possessed by Wasps

MR. CECIL'S letters on "The Power of Stupefying Spiders possessed by Wasps" give details of a fact perfectly well known to entomologists, certainly to all those who have studied the Aculeata; but it is well known to the latter that no true wasp, according to the popular understanding of that name, ever supplies its larvæ with insects stupefied in the manner described. The insects alluded to in Mr. Cecil's letters probably belong to the section of aculeate insects usually known as sand-wasps by naturalists, a very misleading name, since a large number are wood-borers. It would render the subject of stupefying much more understandable to the general reader if this was more clearly elucidated; the general term wasp gives no clue in this instance to the insect observed. We have in this country fossorial insects belonging to the genera Pompilus, Priocnemus,

Agenia, Aporus, Miscophus, Ammophila, Crabro, Cerceris, Philanthus, and some others, all of which stupefy the caterpillars, spiders, or bees, which they store up for the nourishment of their brood, and it would be desirable to have it pointed out to what genera the insects really belong. The species seen by Mr. Cecil, in a collection at Athens, which is described as "a thin-bodied variety," is, I think, a species of the genus Ammophila, or of Pompilus; that observed by Mr. Armit, of Queensland, is probably a species of Pelopæus. Some further definition of the insects I consider highly desirable, as the general term wasp must, I believe, lead to a very false conclusion.

The Expected Meteor Shower

THE meteor shower of Biela's comet, referred to in your "Astronomical Notes" as likely to occur on the 27th inst., should also be looked for on several evenings preceding that date. Last year there were more of these slow-moving *Andromedes* on the 25th than on the 27th of November. On the former night, from 5h. 30m. to 7h., I saw sixteen shooting stars, seven of which belonged to this stream, for they showed a good radiant at R.A. 24° Dec. 45° N. Yet on the 27th only two others were noted out of a total of 10 recorded during a watch from 9h. to 10h. 30m. An occasional look out is therefore advisable on several nights about the 27th, when, if meteors are seen in more than ordinary profusion, it will be important to record their numbers and paths. W. F. DENNING

Geological Climate and Geological Time

IN considering the climatic changes which have evidently taken place on various parts of the earth's surface, it seems to me that what may have been a very important factor has been rather strangely left out of calculation by physicists, never having been noticed hitherto, as far as I am aware. It is that of the heat which must at one period or other have been transmitted from the moon. There can be scarcely a doubt that this must at one time have influenced the earth's climate to a very powerful degree, producing the effects of a second or additional sun. In the absence of any perceptible marks of atmospheric or aqueous erosive action on the moon it is at present impossible to arrive at any idea of its relative age or at what period its heat may have been most abundantly radiated; but if the much hotter climate which once prevailed in northern latitudes could be referred to this cause it might give us some clue to the difficulty. Something also might be done in comparing the various changes of climate which have taken place in certain parts of the earth's surface, as indicated by geological evidence, with the actual course of the moon. The subject is at least worth entertaining, and may be recommended to the consideration of physicists. WILLIAM DAVIES

A "New Galvanometer"

THE galvanometer (with its coil moving about a horizontal axis) described by Dr. Obach in NATURE, vol. xviii. p. 707, is not new. Prof. Pickering has fully described it, under the name of *Cosine* galvanometer, in his "Elements of Physical Manipulation," Part 2 (1876), p. 260. When this instrument was first used I do not know. COMMERCIAL CRISES AND SUN-SPOTS[1]

"Thou Sun, of this great world both eye and soul."

IT is curious to notice the variety of the explanations offered by commercial writers concerning the cause of the present state of trade. Foreign competition, beer-drinking, over-production, trades-unionism, war, peace, want of gold, superabundance of silver, Lord Beaconsfield, Sir Stafford Northcote, their extravagant expenditure, the Government policy, the wretched Glasgow Bank directors, Mr. Edison and the electric light, are a few of the happy and consistent suggestions continually made to explain the present disastrous collapse of industry and credit.

It occurs to but few people to remember that what is happening now is but a mild repetition of what has previously happened time after time. October, 1878, is comparable with May, 1866, with November, 1857, with October, 1847, and, going yet further back, with a somewhat similar condition of things, in 1837, in 1825-26, and even in 1815-16. The incidental circumstances of these commercial collapses have indeed been infinitely diversified. At one time the cause seemed to be the misconduct of the great firm of Overends; in 1857 there was the mutiny in India, the peace with Russia, and a commercial collapse in the United States; in 1847 occurred the Irish famine and a failure of European harvests generally, following upon the great railway mania; the crisis of 1837 succeeded an immense expansion of home trade, the establishment of joint stock banks, and the building of multitudes of factories and other permanent works; 1825 was preceded by extravagant foreign speculations and foreign loans; 1815 was the year of the general peace. All kinds of distinct reasons can thus be given why trade should be now inflated and again depressed and collapsed. But, so long as these causes are various and disconnected, nothing emerges to explain the remarkable appearance of regularity and periodicity which characterises these events.

The periodicity of the earlier portion of the series is so remarkable that, even without the corroboration since received, it convinced scientific inquirers that there was some deep cause in action. Dr. Hyde Clarke, for instance, wrote, more than thirty years ago, a paper entitled "Physical Economy—a preliminary inquiry into the physical laws governing the periods of famines and panics." This paper was published in the *Railway Register* for 1847, and is well worth reading. In the commencement he remarks: "We have just gone through a time of busy industry, and are come upon sorrow and ill-fortune; but the same things have befallen us often within the knowledge of those now living. Of 1837, of 1827, of 1817, of 1806, of 1796, there are men among us who can remember the same things as we now see in 1847. A period of bustle, or of gambling, cut short in a trice and turned into a period of suffering and loss, is a phenomenon so often recorded, that what is most to be noticed is that it should excite any wonder." Dr. Hyde Clarke then proceeds to argue in a highly scientific spirit that events so regularly recurring cannot be attributed to accidental causes; there must, he thinks, be some physical groundwork, and he proposed to search this out by means of a science to be called Physical Economy. In the third page of his paper he tells us that he had previously written a paper on the laws of periodical or cyclical action, printed in Herapath's *Railway Magazine* for 1838. "At this time," he says, "it was my impression that the period of speculation was a period of ten years, but I was led also to look for a period of thirteen or fourteen years. . . . In the course of these inquiries I looked at the astronomical periods and the meteorological theories without finding anything at all available for my purposes." A little below Dr. Hyde Clarke continues:—"Still thinking that the interval was an interval of about ten years, I was, during the present famine, led to look for a larger period, which would contain the smaller periods, and as the present famine and distress seemed particularly severe, my attention was directed to the famine so strongly felt during the French Revolution. This gave a period of about fifty-four years, with five intervals of about ten or eleven years each, which I took thus:—

"1793 1804 1815 1826 1837 1847."

Dr. Hyde Clarke was by no means the only statist who

[1] This article, although treating the same subject, and partially containing the same facts as a paper by the same writer, read at the recent meeting of the British Association, is a distinct composition. The paper in question will probably be published elsewhere.

adopted a theory of periodicity thirty or forty years ago. In February, 1848, Mr. J. T. Danson read a paper to the Statistical Society of London, attempting to trace a connection between periodic changes in the condition of the people and the variations occurring in the same period in the prices of the most necessary articles of food. Mr. James Wilson had published, in 1840, a separate work or large pamphlet upon "Fluctuations of Currency, Commerce, and Manufactures," in which he speaks of the frequent recurrence of periods of excitement and depression. In later years Mr. Wm. Langton, the esteemed banker of Manchester, independently remarked the existence of the decennial cycle, saying: "These disturbances are the accompaniment of another wave, which appears to have a decennial period, and in the generation of which moral causes have no doubt an important share." The paper in which this remark occurs is contained in the *Transactions* of the Manchester Statistical Society for 1857, and is one of the most luminous inquiries concerning commercial fluctuations anywhere to be found.[1] In still later years Mr. John Mills of the Manchester Statistical Society has almost made this subject his own, insisting, however, mainly upon the mental origin of what he has aptly called the Credit Cycle.

The peculiar interest of Dr. Hyde Clarke's speculations consists in the fact that he not only remarked the cycle of ten or eleven years, but sought to explain it as due to physical causes, although he had not succeeded in discovering any similar astronomical or meteorological variation with which to connect it. Writing as he did in 1838 and 1847, this failure is not to be wondered at. His supposed period of fifty-four years is perhaps deserving of further investigation, but it is with his period of ten or eleven years that we are now concerned.

My own inquiries into this interesting subject naturally fall much posterior to those of Dr. Clarke; but, about the year 1862, I prepared two elaborate statistical diagrams, one of which exhibited in a single sheet all the accounts of the Bank of England since 1844, while the other embraced all the monthly statements I could procure of the price of corn, state of the funds, rate of discount, and number of bankruptcies in England from the year 1731 onwards. Subsequent study of these diagrams produced upon my mind a deep conviction that the events of 1815, 1825, 1836-39, 1847, and 1857, exhibited a true but mysterious periodicity. There was no appearance, indeed, of like periodicity in the earlier parts of my second diagram. In the first fifteen years of this century statistical numbers were thrown into confusion by the great wars, the suspension of specie payments, and the frequent extremely high prices of corn. It must be allowed, moreover, that the statistical diagram, so far as concerns the eighteenth century, presents no appreciable trace of decennial periodicity. The recent continual discussions concerning the solar or sun-spot period much increased the interest of this matter, and in 1875 I made a laborious reduction of the data contained in Prof. Thorold Rogers' admirable "History of Agriculture and Prices in England from the Year 1259." I then believed that I had discovered the solar period in the prices of corn and various agricultural commodities, and I accordingly read a paper to that effect at the British Association at Bristol. Subsequent inquiry, however, seemed to show that periods of three, five, seven, nine, or even thirteen years would agree with Prof. Rogers' data just as well as a period of eleven years; in disgust at this result I withdrew the paper from further publication. I should like, however, to be now allowed to quote the following passage from the MS. of the paper in question:—

"Before concluding I will throw out a surmise, which, though it is a mere surmise, seems worth making. It is now pretty generally allowed that the fluctuations of the money market, though often apparently due to exceptional and accidental events, such as wars, great commercial failures, unfounded panics, and so forth, yet do exhibit a remarkable tendency to recur at intervals approximating to ten or eleven years. Thus the principal commmercial crises have happened in the years 1825, 1836-9, 1847, 1857, 1866, and I was almost adding 1879, so convinced do I feel that there will, within the next few years, be another great crisis. Now if there should be in or about the year 1879, a great collapse comparable with those of the years mentioned, there will have been five such occurrences in fifty-four years, giving almost exactly eleven years (10·8) as the average interval, which sufficiently approximates to 11·1, the supposed exact length of the sun-spot period, to warrant speculations as to their possible connection."

I was led to assign the then coming (that is, the now present) crisis to the year 1879, because 11·1 years added twice over to 1857, the date of the last perfectly normal crisis, or to 1847, the date of the previous one, brings the calculator to 1879. If I could have employed instead Mr. J. A. Broun's since published estimate of the sun-spot period, to be presently mentioned, namely, 10·45 years, I should have come exactly to the present year 1878. My mistake of one year was due to the meteorologists' mistake of eight months, which, as crises usually happen in October and November, was sufficient to throw the estimate of the event into the next twelvemonths.

While writing my 1875 paper for the British Association, I was much embarrassed by the fact that the commercial fluctuations could with difficulty be reconciled with a period of 11·1 years. If, indeed, we start from 1825, and add 11·1 years time after time, we get 1836·1, 1847·2, 1858·3, 1869·4, 1880·5, which show a gradually increasing discrepancy from 1837, 1847, 1857, 1866 (and now 1878), the true dates of the crises. To explain this discrepancy I went so far as to form the rather fanciful hypothesis that the commercial world might be a body so mentally constituted, as Mr. John Mills must hold, as to be capable of vibrating in a period of ten years, so that it would every now and then be thrown into oscillation by physical causes having a period of eleven years. The subsequent publication, however, of Mr. J. A. Broun's inquiries, tending to show that the solar period is 10·45 years, not 11·1,[1] placed the matter in a very different light, and removed the difficulties. Thus, if we take Mr. John Mills' "Synopsis of Commercial Panics in the Present Century," and, rejecting 1866 as an instance of a premature panic, count from 1815 to 1857, we find that four credit cycles occupy forty-two years, giving an average duration of 10·5 years, which is a remarkably close approximation to Mr. Broun's solar period. Thus encouraged, it at last occurred to me to look back into the previous century, where facts of a strongly confirmatory character at once presented themselves. Not only was there a great panic in 1793, as Dr. Hyde Clarke remarked, but there were very distinct events of a similar nature in the years 1783, 1772–3, and 1763. About these dates there can be no question, for they may all be found clearly stated on pp. 627 and 628 of the first volume of Mr. Macleod's unfinished "Dictionary of Political Economy." Mr. Macleod gives a concise, but, I believe, correct account of these events, and as he seems to entertain no theory of periodicity, his evidence is perfectly unbiased. Yet, in the space of a few lines, he unconsciously states this periodicity, saying:—"Ten years after the preceding crisis of 1763 another of a very severe nature took place in 1772 and the beginning of 1773. It extended over all the trading nations of Europe." A few lines below he goes on to state that in May, 1783, a rapid drain of bullion to the Continent set in, which greatly alarmed the Bank directors and embarrassed the merchants. The

[1] It is reprinted in the *Transactions* of the same Society for 1875-76.

[1] NATURE, vol. xvi. p. 63.

paragraph in which this occurs is headed "The Crisis of 1783," and on turning the page we at once come on another paragraph headed "The Crisis of 1793." Here then we have, in a few lines of a good authority concerning the history of finance, a statement of four crises occurring at almost exactly decennial intervals. It is wonderful that no writer has, so far as I know, previously pointed out the strictly periodic nature of these events; and I may add that I have several times lectured to my college classes about these crises without remarking their periodicity. It is true that we cannot, by any management of the figures, bring them into co-ordination with later crises so long as we adhere to the former estimate of the solar period. If, starting from 1857, we count back nine intervals of 11·1 years each, we get to 1757 instead of 1763; we are landed in the middle of a cycle instead of in the beginning or end; and there can be no possible doubt about the crises of 1763 and 1857. But, if we are once allowed to substitute the new estimate of Broun, which is the same as the old one of Lamont, the difficulty disappears; for the average interval is 10·44 . . . years!

This beautiful coincidence led me to look still further backwards, and to form the apparently wild notion that the great crisis generally known as that of the South Sea Bubble might not be an isolated and casual event, but only an early and remarkable manifestation of the commercial cycle. The South Sea Bubble is generally set down to the year 1720, and the speculations in the shares of that company did attain their climax and commence their collapse in that year. But it is perfectly well known to the historians of commerce that the general collapse of trade which profoundly affected all the more advanced European nations, especially the Dutch, French, and English, occurred in 1721. Now, if we assume that there have been since 1721, up to 1857, thirteen commercial cycles, the average interval comes out 10·46 years; or if we consider that we are in this very month (November, 1878) passing through a normal crisis, then the interval of 157 years from 1721 to 1878 gives an average cycle of 10·466 years.

It would be impossible, however, to enlist the South-Sea Bubble in our series unless there were some links to connect it with subsequent events. I have, therefore, spent much labour during the past summer in a most tedious and discouraging search among the pamphlets, magazines, and newspapers of the period, with a view to discover other decennial crises. I am free to confess that in this search I have been thoroughly biased in favour of a theory, and that the evidence which I have so far found would have no weight if standing by itself. It is impossible in this place to state properly the facts which I possess; I can only briefly mention what I hope to establish by future more thorough inquiry.

It is remarkable to notice that the South Sea Company, which came to grief in 1720-21, was founded in 1711, just ten years before, and that on the very page (312) of Mr. Fox Bourne's "Romance of Trade,"[1] which mentions this fact, the year 1701 also occurs in connection with speculation and *stock-jobbing*, as the promotion of companies was then called. The occurrence of a crisis in the years 1710-11-12, is indeed almost established by the lists of bubble insurance companies formed in those years, as collected by Mr. Cornelius Walford, and obligingly shown to me by him.[2]

Again, it is quite plain that about ten years after stock-jobbing had been crushed by the crisis of 1721, it reared its head again. A significant passage in the *Gentleman's Magazine* of 1732 (vol. ii. p. 561) remarks that "Stock-jobbing is grown almost epidemical. Fraud, corruption, and iniquity in great companies as much require speedy and effectual remedies now as in 1720. The scarcity of money and stagnation of trade in all the distant parts of England, is a proof that too much of our current coin is got into the hands of a few persons." This "getting the current coins into the hands of a few people" was the favourite theory at that time to explain any slackness of trade, just as now over-production is the theme of every short-sighted politician. But the legislature of that day thought they could remedy these things in a drastic manner, so they passed in 1734 "An Act to prevent the infamous practice of stock-jobbing." Mr. Walford, who has inquired into the commercial history of this time far more minutely than any other writer, remarks[1] that "gambling in stocks and funds had broken out with considerable fervour again during the few years preceding 1734. It was the first symptom of recovery from the events of 1720."

I may add that there was in 1732 a great collapse of a society called the "Charitable Corporation for Relief of the Industrious Poor." A great many people were ruined by the unexpected deficit discovered in the funds of this kind of bank, and Parliament and the public were asked to assist the sufferers, just as they might now be asked to aid the shareholders of the City of Glasgow Bank. Thus does history repeat itself!

Whether it was that the act of 1734 really did diminish the infamous practice of stock-jobbing, or, whether the sun-spots manifested less variation than usual, it is clear that between 1732 and 1763 it is very difficult to discover anything approaching a mania or crisis. My learned and obliging correspondents at Amsterdam and Leiden, Drs. S. and W. Vissering, disclaim any knowledge of such events in the trade of Holland at that time, and my own diagram, showing the monthly bankruptcies throughout the interval, displays a flatness of a thoroughly discouraging character. Nevertheless, inquiry leads me to believe that although there really was nothing to call a crisis, mania, or panic, yet there were remarkable variations in the activity of trade and the prices of some staple commodities, such as wool and tin, sufficient to connect the earlier with the later periods. It is a matter of much regret that I have hitherto been quite unable to discover a connected series of price-lists of commodities of the early part of last century. The accounts of prices of goods at Greenwich Hospital, to be found in several statistical works, are not only incomplete, but probably misleading. Any reader of this article who can point out to me series of prices of metals or other commodities, not merely agricultural, before 1782, will confer a very great obligation upon me by doing so.

Deferring, however, for the present, any minuter inquiry, I permit myself to assume that there were about the years 1742 and 1752 fluctuations of trade which connect the undoubted decennial series of 1711, 1721, and 1732, with that commencing again in the most unquestionable manner in 1763. Thus the whole series of decennial crises may be stated as follows: (1701?), 1711, 1721, 1731-32, (1742? 1752?), 1763, 1772-73, 1783, 1793, (1804-5?), 1815, 1825, 1836-39 (1837 in the United States), 1847, 1857, 1866, 1878. A series of this sort is not, like a chain, as weak as its weakest part; on the contrary, the strong parts add strength to the weak parts. In spite, therefore, of the doubtful existence of some of the crises, as marked in the list, I can entertain no doubt whatever that the principal commercial crises do fall into a series having the average period of about 10·466 years. Moreover, the almost perfect coincidence of this period with Broun's estimate of the sun-spot period (10·45) is by itself strong evidence that the phenomena are causally connected. The exact nature of the connection cannot at present be established. As we have seen, Hyde Clarke, Wilson, and Danson all argued, some thirty or forty years ago, that commercial fluctuations must be

[1] This book contains an interesting account of some of these early manias and panics.

[2] These lists are partly published in Mr. Walford's "Insurance Cyclopædia," article Gambling.

[1] "Insurance Cyclopædia," art. Gambling.

governed by physical causes. But here we are embarrassed by the fact that no inquirer has been able to discover a clear periodic variation in the price of corn. This is what Sir William Herschel attempted to do, at the beginning of this century, in his truly prophetic inquiry about the economic effects of the sun-spots; but his facts are evidently too few to justify any sure inference. Carrington also compared the sun-spot curve with that of the price of corn, without detecting any coincidence; and my own repeated inquiries have been equally without result as to this point. The fact is, I believe, that cereal crops, as grown and gathered in Europe, depend for their success upon very complicated conditions, so that the solar influence is disguised. But it does not follow that other crops in other latitudes may not manifest the decennial period. Dr. Schuster[1] has pointed out a coincidence between good vintages and minima of sun-spots which can hardly be due to accident, and the whole controversy about the connection of Indian famines with the sun-spot period is of course familiar to all readers of NATURE. Now if we may assume Dr. Hunter's famine theory to be true there is little difficulty in explaining the remarkable series of periodic crises which I have pointed out.

The trade of Western Europe has always been strongly affected by communication with the Indies. Several of the crises are distinctly traceable to this cause, especially those at the beginning of the eighteenth century. That was a time of wild enterprise in the tropical regions, as the very names of the South Sea Company, the Mississippi scheme, the Darien project, &c., show. The Dutch, English, and French East India Companies were then potent bodies, the constant subject of legislation and controversy. Thus it is my present belief that to trade with India, China, and probably other parts of the tropical and semi-tropical regions, we must attribute the principal fluctuations in European commerce. Surely there is nothing absurd in such a theory when we remember that the present crisis is at least partly due to the involvement of the City of Glasgow Bank in the India trade, through the medium of some of their chief debtors. Thus the crisis of 1878 is clearly connected with the recent famines in India and China, and these famines are confidently attributed to solar disturbance.

To establish this view of the matter in a satisfactory manner, it would be desirable to show that there has been a decennial variation of trade with India during the 170 years under review. The complications and disturbances produced in the statistics of such a trade by various events are so considerable that I have not yet attempted to disentangle them properly. Yet the accounts of the merchandise (not including bullion) exported by the English East India Company between the years 1708–9 and 1733–34 display such a wonderful tendency to decennial variation, that I cannot refrain from quoting them. As stated by Milburn in vol. i. p. xlviii. of his "Oriental Commerce," they are as given in the following table, except that I have struck off three places of figures useless for our purposes:—

Values of Merchandise Exported to India

Years.	£1000	Years.	£1000
1708–9	162	1721–22	148
1709–10	161	1722–23	135
1710–11	201	1723–24	118
1711–12	162	1724–25	97
1712–13	109	1725–26	80
1713–14	85	1726–27	77
1714–15	79	1727–28	101
1715–16	61	1728–29	102
1716–17	69	1729–30	135
1717–18	88	1730–31	137
1718–19	107	1731–32	150
1719–20	134	1732–33	105
1720–21	122	1733–34	140

[1] NATURE, vol. xvi., p. 45.

In the above table there are three well-marked maxima in 1710–11, 1721–22, and 1731–32 at intervals closely approximating to that of the sun-spot curve. I believe that there are some traces of the same decennial variation in subsequent portions of the same tables. The fact that this variation is difficult to trace may possibly explain the absence of any serious crises in 1742 and 1752.

Probably, however, we ought not to attribute the decennial fluctuation wholly to Indian trade. It is quite possible that tropical Africa, America, the West Indies, and even the Levant are affected by the same meteorological influences which occasion the famines in India. Thus it is the nations which trade most largely to those parts of the world, *and which give long credits to their customers*, which suffer most from these crises. Holland was most easily affected a century ago; England is most deeply affected now; France usually participates, together with some of the German trading towns. But I am not aware that these decennial crises extend in equal severity to such countries as Austria, Hungary, Switzerland, Italy, and Russia, which have comparatively little foreign trade. Even when they are affected, it may be indirectly through sympathy with the great commercial nations.

There is nothing in this theory inconsistent with the fact that crises and panics arise from other than meteorological causes. There was a great political crisis in 1798, a great commercial collapse in 1810–11 (which will not fall into the decennial series); there was a Stock Exchange panic in 1859; and the great American collapse of 1873–75. There have also been several minor disturbances in the money market, such as those of February, 1861, May and September, 1864, August, 1870, November, 1873; but they are probably due to exceptional and disconnected reasons. Moreover, they have seldom, if ever, the intensity, profundity, and wide extension of the true decennial crises.

If it were permitted to draw any immediate conclusion from these speculations, I should point to the necessity of at once undertaking direct observations upon the varying power and character of the sun's rays. There are hundreds of meteorological observatories registering, at every hour of the day and night, the most minute facts about the atmosphere; but that very influence, upon which all atmospheric changes ultimately depend, *the solar radiation*, is not, I believe, measured in any one of them, at least in the proper manner.[1] Pouillet showed long ago (1838) how the absolute heating power of the sun's rays might be accurately determined by his Pyrheliometer. This instrument, and the results which he drew from its use, are fully described in his "Éléments de Physique Expérimentale et de Météorologie" (livre 8me, chap. i., section 285). But I have never heard that his experiments have been repeated, except so far as this may have been done by Sir John Herschel, with his so-called Actinometer, as described by him in the Admiralty Manual of Scientific Inquiry. I fancy that physicists still depend upon Pouillet's observations in 1837 and 1838 for one of the most important constants of the solar system, if constant it can be called. While astronomers agitate themselves and spend infinite labour about the two-hundredth planetoid, or some imperceptible satellite, the very fountain of heat and light and life is left unmeasured. Pouillet indeed assumed that the heating power of the sun's rays is a constant quantity, which accounts for his not continuing the solar observations. But, if there is any truth in all these sun-spot speculations, there must be a periodic variation in the sun's rays, of which the sun-spots are a mere sign, and perhaps an unsatisfactory one. It is possible that the real variations are more regular than the sun-spot indications, and thus perhaps may be explained the curious fact that the decennial crises recur more regu-

[1] Of course there have been abundance of black-bulb thermometer observations made in various parts of the world, but I doubt whether they are of much value.

larly on the whole than the maxima and minima of sun-spots.

But why do we beat about the bush when all that is needed is half-a-dozen of Pouillet's pyrheliometers with skilled observers, who will seize every clear day to determine directly the heating power of the sun? Why do we not go direct to the Great Luminary himself, and ask him plainly whether he varies or not? If he answers No! then some of us must reconsider our theories, and perhaps endure a little ridicule. But if, as is much more probable, he should answer Yes! then the time will come when the most important news in the *Times* will be the usual cablegram of the solar power. Solar observatories ought to be established on the table-lands of Quito or Cuzco, in Cashmere, in Piazzi Smyth's observatory on the Peak of Teneriffe, in Central Australia, or wherever else the sun can be observed most free from atmospheric opacity. An empire on which the sun never sets, and whose commerce pervades every port and creek of the sunny south, cannot wisely neglect to keep a watch on the great fountain of energy. From that sun, which is truly "of this great world both eye and soul," we derive our strength and our weakness, our success and our failure, our elation in commercial mania, and our despondency and ruin in commercial collapse.

W. STANLEY JEVONS

THE WERDERMANN ELECTRIC LIGHT

WE are able this week to give some further details concerning Mr. Werdermann's method of dividing the electric light.

The real difficulty was found in devising a form of *light* which *could* be divided into several, and still give enough illuminating power for practical use; and it is in this particular that Mr. Werdermann has apparently succeeded. It may be interesting here to state Mr. Werdermann's reasons for adopting this particular form of lighting.

When in an electric lamp, electrodes having the same sectional area are used, the changes at the points between which the voltaic arc passes, take place in a manner which is well known, viz., a crater or hollow is formed in the positive electrode which emits the light, the crater itself being heated by the current to white heat, and the surrounding part to redness. The negative electrode which assumes the form of a cone, is only heated to redness, and emits scarcely any light.

It was found that an increase in the sectional area of the positive electrode diminishes the light emitted by that electrode, and if the increase is continued gradually, the light on that electrode finally disappears entirely, whereas the heating effect upon the negative electrode in connection therewith increases, until finally light is emitted by the same. Again, by increasing the sectional area of the negative electrode, the heating effect upon the same decreases proportionally to the increase of its area, until the area having been sufficiently increased the heat almost entirely disappears, and consequently the consumption or wearing away of that electrode is scarcely appreciable.

The light given out by the positive electrode in connection therewith, on the contrary, increases in proportion to the difference existing between the sectional area of the two electrodes, and instead of a crater being formed in the positive carbon, the latter assumes the form of a cone as formerly was the case with the negative carbon. The greater the difference between the areas of the two carbons the shorter is the length of the voltaic arc which can be obtained between them, and when the area of the positive is gradually diminished and that of the negative increased, the light is produced by the carbons apparently in contact, and a small deposit of graphite is seen on the negative electrode. The section of this deposit is about $\frac{1}{4}$ that of the positive carbon itself, and it is about $\frac{1}{8}$ of an inch high.

Mr. Werdermann was led to make these experiments by the idea that perhaps by altering the sectional area of the carbons a similar effect might be produced to that which is obtained in electrolysis when a plate is used as one electrode and a small wire at the other, and from the

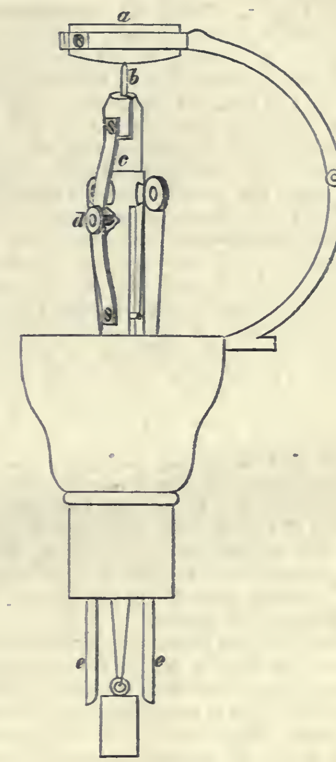

FIG. 1.

results obtained he devised his present system of electric lighting.

His lamp is constructed in the following manner:—

He places the negative carbon which is in the form of a disc 2 inches in diameter, and about 1 inch thick, uppermost. This carbon is clasped all round by a copper band which is prolonged to the terminal to which one of the leading cables is attached. The lower or positive electrode is a small pencil of carbon 3 millimetres in

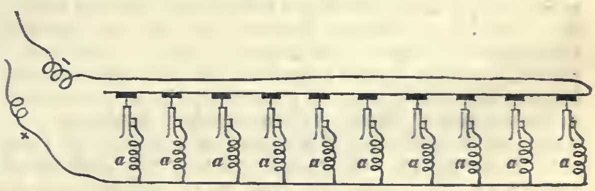

FIG. 2.

diameter, and can be made of any suitable length. This slides up vertically in a tube placed directly underneath the disc. This tube guides the pencil and also forms a contact for it, the top of the tube being solid copper in two pieces, one being rigid and the other pressing against the carbon by means of a regulating spring. The carbon pencil protrudes above the tube about $\frac{3}{4}$ of an inch, and touches the negative disc, and this length when the current passes is made incandescent.

The small carbon is pointed at its upper extremity and retains this point while burning. A small electric arc is formed round the points of junction, and to this is due the greater part of the light and not to incandescence alone. The carbons are kept in contact by chains attached to the lower end of the pencil passing over pulleys and down again to a weight of about 1½ lbs., which is sufficient to keep the pencil pressing gently against the disc.

The sketch, Fig. 1, shows the arrangement of the lamp; *a* is the negative carbon, connected by the semicircular piece of metal *f* to the conductor *e* on the right-hand side which forms part of the lamp-post. The metal *f* is hinged so that the top carbon may be moved back when a globe is put on. *b* is the pencil or positive carbon sliding in the tube *c*, this tube being connected to the conductor *e* on left-hand side. The pressure of the contact upon the small carbon is regulated by the spring *d*. The tube is shown in perspective for greater clearness. The arrangement and details of the lamp being thus shown, we will now describe the experiments which have recently been exhibited at the works of the British Telegraph Manufactory in the Euston Road. The display was mostly of an experimental character, the lamps being somewhat different in construction to those which will be made use of in actual practice, but the principle remains the same. The chief object of the inventor was to demonstrate that a number of lights can be steadily maintained in one circuit. The first experiment tried was that of putting two large lamps such as will be used for street-lighting in circuit with a Gramme electro-plating machine. It may be here remarked that this is probably the first time that such a machine was ever used for the purpose of producing an electric light. The two lamps were said to give a light equal to 360 candles each, but they gave to all appearance a considerably higher illuminating power.

A pure white light was given out, perfectly steady, and showing none of the blue or purple rays observed so frequently in the ordinary form of electric arc. The wonderful steadiness of the light is one of its chief features. After burning for some considerable time the current was switched on to a row of ten smaller lamps arranged on a shelf. The light from each lamp was apparently of the same strength and the effect was very brilliant, but the total illuminating power was not nearly so great as in the case of the two larger ones. But it seemed to show that a form of light had been devised that could be split up into a considerable number of smaller ones, each of which could be made use of in a practical way. The ten lamps were estimated to have a lighting power of forty candles each, but this is probably somewhat above the mark. But the results obtained, both as regards the wonderful regularity of the lamps and the practical demonstration of dividing the light, seem to have been satisfactory; and the more remarkable from the fact of the weak electro-motive force of the machine, which is only equal to that of four Daniell's cells. More lamps could have been lighted even from this machine had they been at Mr. Werdermann's command, but of course with a diminution of light. When suitable machines have been constructed Mr. Werderman is confident of being able to put 50 or 100 lights in circuit, but he does not believe in the indefinite division of the current for lighting purposes.

The lights were all connected parallel, as shown in diagram, Fig. 2. The thick wires + and − connect the lamps with the machine, the first lamp on the + cable being last on the − wire. The spirals *a* are extra resistances put in the circuit of each lamp, the object being to render the divided current less sensitive to any slight variation in the resistance of the lamps themselves, due to unequal pressure of contact, &c. The resistance of each lamp, including the wire *a*, is about 0·39 ohms. The resistance of the ten in parallel circuit about 0·037 ohms. The carbon pencil consumes at the rate of from 1½ to 2 inches per hour in the small lamps; the large ones taking 4½ millimetre carbons, consume about 2½ or 3 inches in the same time. The pencils are made in Paris, costing about 1 franc per yard, which length will last for twelve hours. The discs are of ordinary carbon.

However many lights may be in use, one, two, three, or any number can be put out without affecting the others, the regulation of the current being provided for by a switch attached to each lamp. But if necessary, the current which originally went through those that are extinguished can be added to those kept alight, of course increasing their illuminating power. The lamps are set in action simultaneously, can be as easily put out, and again re-lighted.

Returning again to the intensity of the light, it was stated that the large lamps were equal to 360 candles. Now the effect of this light upon the eyes is apparently not injurious, and it is Mr. Werdermann's intention to use only globes of ordinary glass, as in the present form of gas-lamps; by this means the loss of light will be very slight indeed as compared with other systems, where the loss is from 20 to 30 per cent., incurred by using opal or ground glass globes.

Owing to the very small electromotive force of the machine the insulation of the cables can easily be provided for, and Mr. Werdermann hopes, with sufficiently powerful machines, to be able to carry the current to a considerable distance without any appreciable loss.

In conclusion, it may be worth while giving a few details in regard to the Gramme machine used. It is an electro-plating machine of the old pattern, having four upright electro-magnets and two bobbins, one for feeding the electro-magnets, the other for taking off the light-producing current. The bobbins are wound with thick copper bands. The electromotive force, as before stated, is only equal to four Daniell's cells, and the resistance of the taking-off bobbin is about 0·008 ohms. The quantity of current produced is of course large.

It may be mentioned that the large lamps were connected parallel, but having no extra resistances, as in the case of the 10; their resistance is also a trifle less. The resistances given are when the lamps are not alight; when burning it would be somewhat less. The power required to drive the machine described is about two horse-power.

A curious fact about the light is that the top carbon is not consumed, or at any rate so slowly, that it is not noticeable; therefore, to all intent and purpose, the lower carbon only is wasted.

T. E. GATEHOUSE

DUPLEXING THE ATLANTIC CABLE

THE simultaneous transmission of two telegraphic messages in opposite directions upon one wire, now known by the name of duplex telegraphy, dates back from the year 1853. In that year Dr. Gintl, the director of state telegraphs in Austria, described a method by which this feat could be accomplished, and in July of the same year the method suggested by Gintl was tried between Prague and Vienna. An improvement on this method was suggested by a German electrician, Frischen, by Messrs. Siemens and Halske, of Berlin, and other workers at this subject. Nevertheless, owing to practical difficulties, the experiments were little more than interesting additions to our knowledge. So little hope, indeed, was there of the practical realisation of this important matter that, in a standard work on telegraphy, published in 1867, after describing the early methods of duplex telegraphy, the author remarks:—"Systems of telegraphing in opposite directions and of telegraphing in the same

direction more than one message at a time must be looked upon as little more than feats in 'intellectual gymnastics,' very beautiful in their way, but quite useless in a practical point of view." Such assertions should teach all scientific writers the lesson of "hoping all things not impossible, believing all things not improbable," an attitude of mind which, Sir John Herschel remarks, should always characterise the natural philosopher, and which, in the present day, is certainly the safest one. Within six years of the publication of the foregoing statement duplex telegraphy was not only largely employed in actual telegraphy, but its use on certain busy lines became absolutely indispensable. The change from theoretical to practical success is due to an American, Mr. J. B. Stearns, who in 1872 succeeded in overcoming the main obstacle in duplex telegraphy, namely, what is known as the static discharge from the line. This Stearns accomplished by using a "condenser"; and further he developed a system of "duplexing" the line similar to the principle of the Wheatstone bridge.

FIG. 1.

FIG. 2.

More or less successful attempts were afterwards made to duplex submarine cables, and in the early part of 1877 Mr. J. Muirhead succeeded in duplexing the cables of the Eastern Telegraph Company by his artificial condensers. But we believe that his success was only partial. Subsequently Mr. Muirhead has been at work duplexing the Direct United States Cable with some prospect of success, and this week Stearns, who may be called the father of duplex telegraphy, has actually achieved the great feat of perfectly duplexing the Anglo-American Cable. In a message received by Mr. W. H. Preece this week, Mr. Stearns says, "I managed to get some

FIG. 3.

specimens for you this morning, though we had no time to make the balance *especially* perfect for the purpose. No. 1 shows signals received single; No. 2, ditto, duplex. No one can tell the difference. No. 3 is our balance while keying, but not receiving. No. 4 shows the balance perfect at first, but destroyed and restored again by the adjuster. It shows with what facility the ordinary adjustments can be made after the balance is once obtained. The whole time occupied by slip No. 4 was about twenty seconds."

To understand these drawings our readers must know that all the messages now sent across the Atlantic are

FIG. 4.

automatically registered by means of Sir W. Thomson's delicate and beautiful siphon recorder, which spirts out little jets of ink in a fine stream on a moving ribbon of paper. When no current passes the ink-marks form a straight line, but a current causes this line to deviate to the right or left, according to the direction of current. Hence the ordinary right and left strokes of a needle instrument or the long and short dashes of a Morse are here indicated by marks above and below the middle line. Thus the balance is shown by the almost perfectly straight line in Fig. 3 and the messages in Figs. 1 and 2.

The essence of duplex telegraphy is to obtain an electrical balance round on the line such that the sending instrument is not affected by currents circulating round it coming from the sending end, but only by currents received from the opposite end, and *vice versâ*. Hence, if the balance be once obtained, double transmission is possible. This balance Stearns has succeeded in obtaining by the use of his system as applied to land lines, and without the aid of the additional arrangements of artificial condensers used by Dr. Muirhead.

THE ROYAL SOCIETY MEDALLISTS

THE following are the awards of medals by the Council of the Royal Society for the present year. The medals will be given away at the Society's anniversary meeting on the 30th inst.:—The Copley Medal to M. Jean Baptiste Boussingault for his long-continued and important researches and discoveries in agricultural chemistry; a Royal Medal to Mr. John Allan Broun, F.R.S., for his investigations during thirty-five years in magnetism and meteorology, and for his improvements in methods of observation; a Royal Medal to Dr. Albert Günther, F.R.S., for his numerous and valuable contributions to the zoology and anatomy of fishes and reptiles; the Rumford Medal to M. Alfred Cornu, for his various optical researches, and especially for his recent re-determination of the velocity of propagation of light; the Davy Medal to MM. Louis Paul Cailletet and Raoul Pictet, for their researches, conducted independently but contemporaneously, on the condensation of the so-called permanent gases.

Jean Baptiste Boussingault was born in Paris in 1802. He was educated at the Mining School of St. Étienne, after leaving which he became connected with an English company formed to recover and work some mines in South America. This project, however, turning out unsatisfactory, after a considerable time spent in scientific travel in that continent, he returned to France and commenced those researches with which his name is more closely allied, the most important of which lie in the domain of agricultural chemistry. Probably his investigations of greatest value are those in which he has determined the quantities of carbon, nitrogen, and hydrogen found in plants, and his comparison of these with the amounts of the same constituents supplied to the plant by manures, &c. During these investigations he has shown, by a series of most conclusive experiments, the inaccuracy of the theory "that plants in their growth

derive nitrogen from the air," but, on the contrary, has pointed out that all the nitrogen assimilated by them may be accounted for in the different compounds of that body which are supplied to the plant in other ways. Boussingault's experiments also on the nutritive properties of the nourishment supplied to herbivorous animals are of great interest. In these he has traced the distribution of the various constituents of the food by the vital process, and has determined the different quantities of the various constituents which undergo assimilation. Besides investigations in the directions just indicated, he has introduced various improvements in methods of analysis, and has published many valuable articles, most of which are collected in his "Mémoires de Chimie Agricole et de Physiologie;" he has also written a work entitled "Traité d'Economie Rural."

With the work of Mr. J. Allan Broun most of our readers must be familiar. On the commencement of magnetic observations he indicated the errors or insufficiencies of the methods for determining coefficients and correcting the observations issued by the committee of the Royal Society for the instruction and direction of superintendents of observatories; he devised new methods for these ends which have made the observations in all the magnetic observatories available for strict scientific conclusions. He has made investigations in magnetism and meteorology during thirty-five years; among the new results obtained many of them are of the highest value, and have taken their place as standard scientific data. He established an observatory twice on a mountain-peak 6,000 feet above the sea, with the complement of instruments employed in first-class observatories (on the second occasion with a double series of magnetical instruments)—this, in a wild country, done amidst great difficulties in erecting instruments and obtaining trained observers, requiring continued and persevering action. This and many other duties were done at his own expense, and though, in general, ultimately repaid, they yet included considerable pecuniary loss. He also spent his own means in obtaining new instruments, and in every matter likely to forward science. He has laboured for years without remuneration in scientific work of a peculiarly tedious kind.

Albert C. L. G. Günther is the Keeper of the Zoological Department of the British Museum, a position to which he succeeded on the death of Dr. J. E. Gray. Very early in his life he devoted himself to the study of the natural sciences, and, if we are not mistaken, his earliest essay as an author was a very complete memoir of the fishes of the Neckar. About 1854 he accepted an appointment in the British Museum under Dr. J. E. Gray, who soon learned to value and appreciate the services of his assistant. Dr. Günther commenced the investigation and arrangement of the batrachian reptiles in the National Collection, with a zeal and energy that knew no limits, and which soon rendered this portion of the Zoological Department without a rival among the Museums of Europe. Not wearied by such a task he set about a far greater one, the arrangement and description of the immense class of the fishes, and no zoologist has ever raised a greater or more enduring monument to his memory than Dr. Günther has done in his great and truly scientific catalogue of all the known fish. The care of a large and daily-increasing collection, with all the worry incident on the want of room to properly store it—the toil and labour involved in the publication of the extensive work just alluded to, might well have excused Dr. Günther from attempting other work, but still we find him apparently never weary, and memoirs of a value like those on Hatteria, on Ceratodus, and on the Giant Tortoises, not to mention a long list of others, were being constantly published by him. He is also the author of an important work published at the expense of the Ray Society, "On the Reptiles of British India," and joint author with Col. Playfair of a work on the "Fishes of Zanzibar." All will agree that his name is a very worthy one to be added to the grand roll call of the Royal Society's medallists.

The name of M. Alfred Cornu must be familiar to the readers of NATURE in connection with his remarkably ingenious and successful method of determining the velocity of light. A detailed account of M. Cornu's method will be found in vol. xi. p. 274, and succeeding volumes of NATURE. It was also expounded by him, it may be remembered, at the Royal Institution, on May 7, 1875. The important bearings of M. Cornu's experiments in various directions, we need not point out; its value in attaining an accurate estimate of the sun's parallax is evident. As is evidenced by the *Comptes Rendus*, M. Cornu's work in his own department is constant and varied; his research into the spectrum of the star that appeared in Cygnus two years ago was a fine example of the result of spectroscopic research; an account of it will be found in NATURE, vol. xv. Although probably the youngest of the new medallists, M. Cornu's long and incessant work makes him almost a veteran in scientific research.

MM. L. Cailletet and Raoul Pictet have lately been so closely engaged in the same kind of experimental work, namely, the liquefaction of gaseous bodies, that their names have naturally become associated in connection with the important results which have followed their independent researches. The methods, however, employed by the two chemists in obtaining those results which have lately added so much to their reputation are to a certain extent different. Cailletet's experiments, which were conducted on the gases air, hydrogen, marsh gas, nitric oxide, and carbonic oxide, depend for the cold necessary to produce the liquefaction of the gas, on the expansion of the gas when suddenly compressed only at moderate degrees of cold.

Pictet's experiments, on the other hand, are the result of his endeavours to discover improved methods for producing and maintaining for a considerable time very low degrees of temperature. Combining these improvements with the production of the bodies to be liquefied under great pressure, he has succeeded in liquefying oxygen and hydrogen and in solidifying the latter. He has also determined the specific gravities of the gases when in that condition, assigning to them the weights ·9883 and ·9787. Besides his most recent researches on the condensation of gases, M. Pictet has carried out other investigations on those phenomena, the consideration of which lies between the provinces of physics and chemistry. Among such investigations may be mentioned his observations on the application of the mechanical theory of heat to the study of volatile liquids and to some simple relations between the latent heats, atomic weights, and tensions of vapours. M. Pictet has also been successful in applying his scientific investigations to practical use, in the perfecting of apparatus for the rapid production of large quantities of ice.

We are glad to know that the health of M. Pictet is not so seriously impaired by overwork as was rumoured a few days ago. On the best authority it is stated that his recovery is by no means beyond hope, and that he is not suffering from incipient softening of the brain. There is no contradiction, however, to the sad statement that the sight of one of M. Pictet's eyes is gone, and that he will probably lose the power of the other.

AFGHANISTAN

WHATEVER opinions our readers may hold as to the present action of the Government with respect to Afghanistan, it may not be considered inappropriate to summarise briefly what we know about a country, which at no remote date may become a part of the British

Empire. A good deal has been written on the country, and some valuable records of the observations of travellers who have been permitted to penetrate it have been published. One of the best sketches of Afghanistan in its various aspects will be found in the magnificent "Noveau Dict. de Géog. Universelle," by Vivien de St. Martin, now being issued by Hachette and Co. On this the present article is mainly based. For further details we would refer our readers to this work, and the long bibliography appended to the article, as well as to a paper in the *Geographical Magazine* for October, and a pretty exhaustive account of the botany of the country in the *Gardener's Chronicle* of November 2, and the works referred to in these two journals.

As a whole, Afghanistan may be regarded as a mountainous table-land. It is the eastern half of the table-land of Iran, of which Persia occupies the western half. On the eastern side, towards Sind, the table-land sinks into what may be considered as parallel chains, forming so many staged terraces; one of these chains, more elevated than the others, and from which shoot several remarkable peaks, is known by the name of the Sulieman Mountains—*Soleimân-Kôh.* The mean height of this transverse chain is about 9,000 or 10,000 feet. The Sulieman Mountains are about sixty miles distant from the Sind border, though the crest of the plateau is not reached for about another 150 miles. On the south side the plateau descends by similar, but perhaps less pronounced gradations, towards the sea; up to the present time the southern slope has been but incompletely explored. To the west the Afghan plateau undergoes a very considerable depression, at the bottom of which lies the marshy lake, Hamoun, into which the Helmand river finds its way; but it again rises in the vast plains which lead towards Farsistan. On the north the plateau falls rapidly towards the plains through which flows the Oxus, and in the north-east it is connected with the highlands of Central Asia and the Himalayas by the enormous mass of the Hindu-Koosh. The highest summits of the latter chain, which conceals the deep basin of the Cabul river, are lost in the regions of eternal snow; many of its peaks exceed 20,000 feet in height. The Khavak Pass, one of the principal passes of the Hindu-Koosh, is at a height of more than 12,000 feet. On the south the basin of the Cabul river is shut in by the Sefid-Kôh chain, which runs, like the Hindu-Koosh, from west to east, and the highest summits of which, to the south-south-east of Jellalabad, reach a height of more than 13,000 feet. The source of the Cabul river is about 8,000 feet above the sea, and of the Helmand, more than 9,000 feet. All this extreme zone of Afghanistan is only a mass of mountains cut by a multitude of rugged valleys; this is the coldest part of the country. A mass which dominates it, above the sources of the Cabul and the Helmand, the Kôh-i-Baba or "Father of Mountains," rising to a height of 15,000 feet, may be regarded as the knot which connects the Hindu-Koosh with the Mountains of Ghour. It is in this cold region, which commences at the Mountains of Ghour and is continued eastward by the long valley of the Cabul river, that the primitive race of the Afghan people have been formed, a race uncultured, rude, and vigorous like their native valleys.

With the exception of the two basins of the Cabul and the Helmand, Afghanistan is characterised by a scarcity of running water. Elphinstone had noticed this prevailing feature, and all subsequent observations have confirmed it. Only four or five rivers of any consequence flow down the long eastern slope of the plateau, and some of these are lost in the sands. The Helmand, fed by many affluents, after a course of about 600 miles, discharges into a large shallow lake, nearly all covered with reeds. This lake, known variously as Hamoun, Meshileh-Seistan, or Meshileh-Rustem, is black and nauseous, changes greatly in its configuration, sometimes even dividing up into two distinct basins.

Four-fifths of the surface of Afghanistan is, on the whole, a country of rocks and mountains, interspersed here and there with picturesque valleys, fertile and well watered, but presenting in several directions only elevated plains, cold, arid, and covered with meagre pasturage, which, however, supports numerous flocks. Situated under the parallels of Egypt and Syria, but with a surface not less varied than that of Switzerland, and mountains much more elevated than the Alps, Afghanistan combines in its climate and its products the extremes of the torrid and temperate zones. As the meagreness of its water-supply is characteristic of many parts of the country, dryness is the dominant feature of its climate, as also extremes of temperature, according to the season.

Of the geology of Afghanistan scarcely anything is known by direct observation. Its mineral products, however, appear to be abundant enough. The sands of the Cabul river are known to furnish gold. The Hindu-Koosh mountains contain silver, copper, cinnabar, lead, antimony, zinc, sulphur, &c. Iron especially abounds there, and copper is found in many other parts of the country; coal also has been proved to exist in several localities. Rock salt has given its name to an entire chain of mountains which stretch into the north of the Punjâb. In the north of Damân, in the neighbourhood of Kohat, are mines of sulphur and wells of naphtha.

The character of the vegetation in all the higher parts of Afghanistan is essentially European; all kinds of fruits abound, and many of them are found in a wild state. From the article on the botany of Afghanistan in the *Gardeners' Chronicle* of November 2, we find the following statement as to the general characteristics of the vegetation of the country:—

"Afghanistan abounds in spiny plants; herbs are to a great extent replaced by dwarf prickly shrubs having a relatively small amount of leaf-surface; and bulbous plants are also numerous. Fragrant flowers prevail, and resiniferous and oleiferous plants are numerous. Stocks, who travelled in Beloochistan and the southern borders of Afghanistan, says the upper region especially is remarkable for the fragrance of its plants, as Artemisia, Perowskia, Salvia, Teucrium, and other Labiatæ, from which cause the flesh of the sheep and goats acquires a fine and almost aromatic flavour. There is no nakedness of the soil, for hill and plain are alike covered with depressed shrubs, although their scorched aspect, after the sun acquires power in June, is anything but agreeable to the eye. The prevailing tint of the indigenous vegetation and of the landscape of the uncultivated plains is olive-green, though the well-cultivated valleys, as Quettah, are charmingly green in the spring time. The aspect of the vegetation of the lower region is far different, the plants being few and scattered over the bare brown and stony soil. Even in spring no annuals appear to diversify the scenery, and the under-shrubs are remarkably similar in external appearance. Woody, stunted, thorny, not above 1 foot high, with round cushion-like outlines, bleached stems, and a few leaves—they look like skeletons of plants, the grey ghosts of a vegetation which has perished of thirst. The glaucous aspect of all, and the universality of spines, are noteworthy features."

Wild animals are not over-abundant. The high valleys of the Hindu-Koosh shelter lions and leopards, which have neither the size nor ferocity of those of India. Wolves are met with, and in the eastern jungles tigers and hyænas. There are two species of bear, a black and a brown, but elephants are not found in the wild state. Jackals and foxes are numerous, monkeys in the north-east, and wild sheep and goats in the mountains of the north. The Angora cat is said to have originally come from Cabul.

There is probably no country of equal extent which

presents so great a mixture of races, though the two main divisions are Afghans proper and Tajiks. The former name is applied to all those tribes that speak Pushtu or Pukhtu, the other to those of the people whose native language is Persian. To the latter are also given the names Parsivân and Deggän or Dekkân. The Afghans are mostly pastoral, while the Tajiks are sedentary and cultivate the soil. To these two great classes must be added the Hindkis, of Hindu origin, and speaking Hindustani, very numerous in the eastern districts; also the Hezareh, a people with Mongol features but speaking Persian, found mainly between Ghazna and Herat. The Kisil-bash or "Red Heads," although not very numerous, are an important factor in the population. They are not Persian by origin, as is commonly stated, but belong to one of the Turcoman tribes of Persia. There has been much discussion as to the origin of the Afghans, no doubt the true aborigines of the country. Some have sought to find in them the descendants of the captive ten tribes of Israel; but this is a mere fanciful Mussulman tradition. Their language, at least, proves that they belong to the great Indo-European family, and that in this family they are specially allied to the Iranian group, but with a linguistic development peculiar to themselves, showing also the influence of Sanscrit. Moreover, it can be conclusively established, both by historical and ethnological evidence, that from the most ancient times the Afghans have inhabited the basin of the Cabul river, which is still the principal seat of the race. The true national name of the Afghan people, the name recognised by themselves, is that of Pashtoûn, Pakhtoûn, or Poukhtanêh. In physical type the Afghans, like all the other peoples of Western Asia, approach the European conformation; the difference being in physiognomy, not in type. Like most other primitive peoples, the social organisation of the Afghans is based on the tribe or clan, and in many respects, it has been said, resembles the old clan system of the Scottish Highlands.

OUR ASTRONOMICAL COLUMN

THE SOLAR ECLIPSE OF 1879, JULY 19.—Though the second of the solar eclipses of next year will not be actually total at any point upon the earth's surface, the difference between the geocentric diameters of sun and moon is sufficiently small to allow of the effect of the augmentation upon the latter, bringing up the phase to one nearly approaching totality in those parts which have the sun close upon the meridian. In the longitude of Aden, or rather, upon the opposite coast of Africa, about Zeyla, the moon's augmented semi-diameter will be only four seconds less than that of the sun, and though the eclipse thus remains annular, it will be seen that the annulus is very narrow in this part of its path—including its passage across Abyssinia. At Aden, there will be a very large eclipse, beginning at 10h. 23m. A.M., local mean time, and ending at 2h. 1m. P.M.; at greatest phase about 0h. 12m., the magnitude will be 0·97 of the sun's diameter. The difference between the illumination of the sky while any portion, no matter how small, of the direct light of the sun remains, and the instant it is entirely extinguished in a total eclipse, is so great as we know from our experience of total eclipses, that there may probably be a doubt as to the possibility of utilising the eclipse in question, in a further endeavour to observe the intra-mercurial planet or planets discovered by Prof. Watson. The next total eclipse of the sun will take place on January 11, 1880, and although, notwithstanding the long track of the shadow across the Pacific Ocean, it may be possible to secure observations, the interval available for so doing cannot be more than half that at the command of observers during the eclipse which traversed the United States last July.

COMETS OF SHORT PERIOD.—An ephemeris of Brorsen's comet, which, according to the calculations of Prof. Schulze, will arrive at perihelion on March 30, 1879, will be found in *Astron. Nach.*, No. 2,220; as already stated in this column, it is likely that the comet will be first observed at the southern observatories. About six weeks later Tempel's comet, 1867 II, which was re-observed in 1873, after undergoing great perturbation from the planet Jupiter, will be due at perihelion; the elements deduced from the observations of 1873 alone, by Dr. Sandberg, would assign, without taking account of perturbation, April 26 for the perihelion passage, but according to an orbit just published by M. Raoul Gautier, of Geneva which he says may be considered the most probable one till the observations to be expected next year, afford additional means of determining the mean motion, the comet would not be in perihelion till May 8, in which case its apparent track in the heavens will differ little from that which it pursued in 1873, when it arrived at its least distance from the sun on May 9. It is pretty sure to be always a faint object except for the larger telescopes, and considering the uncertainty which still appears to exist regarding the mean motion at its last appearance, a close search may be necessary for its rediscovery. M. Gautier is calculating the effect of Jupiter's attraction during the actual revolution, with the intention of publishing an ephemeris in due time; this effect, however, must be small, as the comet has not been nearer to the planet than about 1·5 during the interval. The ensuing return of Faye's comet in the latter part of the year 1880 will take place under much more favourable circumstances for observation than has been the case at any of its appearances since 1843, when it was first detected by the French astronomer; indeed, in 1851, 1858, 1865–66, and 1873 it was always a faint object, but the admirable calculations of Dr. Axel Möller have enabled us to follow its course with extreme precision, with a precision perhaps greater than has yet attended similar investigation in the case of any other comet during so long a period. Though the date of perihelion passage is not yet exactly ascertained, the comet will probably approach almost as near to the earth as in the autumn of 1843, and will be observable for many months.

THE SATURNIAN SATELLITE MIMAS.—According to elements which represent approximately the Washington observations, 1874-77, the following will be times of greatest eastern elongation of Mimas:—

	h.		h.
November 15 at	12·3	November 18 at	8·1
,, 16 ,,	10·9	,, 19 ,,	6·7
,, 17 ,,	9·5		

At these times, on the assumption of circular motion, the distance of the satellite from the end of the ring would be about 8′.

THE MINOR PLANET ISMENE.—According to a calculation of the elements of the small planet *Ismene*, No. 190, by Herr Leman, from observations between September 30 and October 31, it very closely approaches *Hilda*, in its exceptionally great distance from the sun, and consequent length of the period of revolution. We have for comparison:—

	Ismene.	*Hilda.*
Mean distance	3·893	3·950
Aphelion distance	4·466	4·595
Sidereal period in days ...	2·805	2·855
,, ,, years ...	7·68	7·85

Another group is formed by *Cybele*, *Freia*, *Sylvia*, *Camilla*, and *Hermione*, wherein the periods vary from 2297 days to 2377, the mean distance for the group, 3·451. Eventually the planets which approach so near to the orbit of Jupiter, as *Ismene* and *Hilda*, will furnish independent determinations of his mass, though the narrow limits of probable error, within which its value

has been determined by Bessel, Krueger, and Axel Möller, may detract from the importance of further investigation in this direction. Thus the sun's mass exceeds the mass of the planet,

1047·88 times according to Bessel, from elongations of fourth satellite.

1047·54 times according to Krueger, from perturbations of *Themis.*

1047·79 times according to Möller, from perturbations of *Faye's Comet.*

GEOGRAPHICAL NOTES

THE following form the series of scientific lectures to be delivered before the Royal Geographical Society during the present session, in pursuance of the scheme organised by the council two years ago:—"Geographical Evolution," by Prof. Geikie; "The Flora of the European Alps and its Connection with that of other Regions of the Earth," by Mr. John Ball, F.R.S.; and "The Modifications of the External Aspects of Organic Nature produced by Man's Interference," by Prof. Rolleston. The first two will be delivered some time before Easter, next year, and the last probably on the second Monday in May.

IN the absence of Lord Dufferin, the session of the Geographical Society was opened on Monday night by an address from Sir Rutherford Alcock, who reviewed recent exploring work.

AT the opening meeting of the Royal Geographical Society a paper by Signor L. M. d'Albertis, the well-known Italian naturalist, was read, descriptive of his three journeys up the Fly River, and his explorations of other parts of New Guinea. Perhaps the most interesting part of this very interesting paper was that which related to his earlier work when in company with Dr. O. Beccari in 1872. On that occasion they landed first on Sorong Island, between Salwatti and the mainland of New Guinea, in about S. lat. 0° 25′, and after making collections of plants and animals there, they moved on to Andai, near Dorei. During their stay there Signor d'Albertis explored the country to the foot of the high chain of mountains named Lapi Arfak. No one hitherto had been able to penetrate to the Arfak highlands, the home of the bird of paradise, and it is doubtful if the attempt had ever been made, owing to the fear entertained by the coast natives of the mountain tribes. Signor d'Albertis, however, succeeded in accomplishing this feat, for he lived for a month in a Papuan house at a height of 3,600 feet above the sea, and in the course of his daily shooting expeditions reached an altitude of 5,000 feet; so that with pardonable pride he claims to have been the pioneer of the Arfak mountains. Judging by the altitude he attained, he considers that the estimated height of the range—9,000 feet—is no exaggeration. From the point which he reached, 5,000 feet above the sea, the range runs uninterruptedly in a southerly direction, and joins that which constitutes the chief part of the backbone of New Guinea. As far as he could judge, separate streams issue from these ranges, giving origin to many small rivers which disembogue in the two bays known by the name of Geelwink. The mountains, even at the highest point he attained, are clothed with magnificent arboreal vegetation, but he was much astonished to find amongst the trees a species of oak and a conifer, the latter of which was afterwards recognised by Dr. Beccari as an *Araucaria.* Another point is worthy of notice; within a few minutes of the equator, in 134° E. long., all the climates of the world, except the Arctic, are represented, the tropical at the base and the temperate on the upper slopes and summits, both of which offer a rich variety of trees and plants. The same description applies to the neighbouring mountains where exist the most beautiful species of birds of paradise known to the world. In his second expedition Signor D'Albertis spent some time at Yule Island, on the southern coast, near Port Moresby, and he expresses a very decided opinion that this place will be of great importance as a centre of trade in the future.

A LETTER from Mr. Andrew Goldie is published in the *Sydney Morning Herald,* in which he gives some account of a cruise along the south-east coast of New Guinea. Mr. Goldie found the currents and calms a great source of danger. On the way down the coast Mr. Goldie discovered a group of islands (Redlich Group) not marked on the chart, and two splendid harbours, the finest by far that he has seen in New Guinea. He names them Glasgow and Millport harbours, and he has taken soundings and drawn plans, which he intends to forward to the proper quarter. The party visited Cloudy Bay and ascended the Robinson River, taking soundings there and all through the bay, and correcting many errors on the Admiralty chart. They discovered a new river on the west side of Cloudy Bay, which has been named the Blunden. During this trip Mr. Goldie has evidently not overlooked one of the main objects of his being sent to New Guinea, for he has collected 100 fresh skins of birds, different from those in the neighbourhood of Port Moresby, and he has also obtained a large and very valuable collection of curiosities.

THE late Admiral Sir George Back, who was for some time one of the vice-presidents of the Royal Geographical Society, has bequeathed to that body the sum of 600*l.* to be invested in Consolidated Bank Annuities, the conditions attached to the bequest being that the interest shall be paid or applied annually "to or for the benefit of such scientific geographers or discoverers, or person or persons who may then be engaged in discovery or exploration, and in such manner and form as the president and council shall determine." It is further provided that if in any year no person shall be deemed of sufficient merit to receive the prize, the interest shall accumulate and in some succeeding year be awarded to one or more persons who may be considered most deserving, in such proportions as the president and council of the Society may determine. Sir George has also bequeathed to the Royal Geographical Society a very characteristic portrait of himself painted many years ago by Brockeden.

MR. KEITH JOHNSTON, the commander of the expedition despatched by the Committee of the African Exploration Fund to explore the country between the road now being constructed from Dar-es-Salaam, on the east coast of Africa, and the north end of Lake Nyassa, leaves for Zanzibar to-day, in company with Mr. Joseph Thomson, as geologist and naturalist, and great hopes are entertained that, in addition to achieving good geographical results, they will be able to furnish much information respecting the hydrology and geology of the unknown region they are about to explore. Should the financial position of the fund admit of it, Mr. Johnston will extend his explorations northward to Lake Tanganyika, and return to the coast by a different route.

THE arrival at Provincetown, Massachusetts, on October 26, of the Arctic exploration schooner *Florence,* Capt. George Tyson, relieved the anxiety felt for her safety, after her reported departure on September 26, from St. John, New Brunswick. The *Florence* has met with hard usage throughout her whole voyage, and officers and men have suffered considerably. According to the log, the coldest weather experienced was 53° below zero.

M. LIAIS, director of the Rio de Janeiro Observatory, has written to the Paris Geographical Society, intimating that, owing to the liberality of the Emperor of Brazil, he had been enabled to begin the great work of determining by electric telegraph the longitude of Rio in comparison with Greenwich. When the operation shall have been

completed, the geographical position of every city in Southern America will be known with exactitude.

THE Annual Meeting of the Dutch Geographical Society took place at Delft on October 27, when interesting communications were made by the president regarding the exploring expedition sent to Sumatra by the Society. The explorers report having passed through a number of districts which had never been visited before by Europeans, but through the resistance offered by one of the native chieftains, the expedition has now unfortunately been discontinued, and most of its members are on their way back to Holland.

IT is stated that the Russian Minister of Communications will shortly send a special expedition to the Amu Darya district, to describe the new waterway formed by the overflow of that river.

THE *New York Herald* publishes a complete list of positions on the Amazon and Madeira rivers which have been determined by the United States Survey Expedition in the corvette *Enterprise*, Commander Selfridge. They are ninety-two in number. The survey has demonstrated that it is possible for vessels drawing sixteen feet of water to pass during nine months of the year, and by careful navigation during the whole year, up to St. Antonio, on the Madeira. The river is always practicable for vessels drawing only eight feet. The Upper Madeira is not safely navigable except between December and July. Every evening the officers specially charged with the duty landed and ascertained the latitude and longitude of the halting-place, with reference also to its bearings with respect to certain conspicuous stars north and south, east and west. Six careful sets of observations, at intervals, were made to determine the rate of the chronometer. The charts compiled are to be reduced and published at Washington.

NOTES

WE take the following from the *Times*:—At the meeting of the Council of the Royal Society on Thursday last, the following were nominated as council and officers for the year ensuing to be proposed for election at the anniversary meeting of the Society, which will be held on St. Andrew's Day, the 30th instant:—President, William Spottiswoode, M.A., LL.D.; Treasurer, John Evans, F.G.S., V.P.S.A.; Secretaries, Prof. George Gabriel Stokes, M.A., D.C.L., LL.D., and Prof. Thomas Henry Huxley, LL.D.; Foreign Secretary, Prof. Alexander William Williamson, Ph.D. Other Members of the Council—Frederick A. Abel, C.B., V.P.C.S., William Bowman, F.R.C.S., William Carruthers, F.L.S., Major-Gen. Henry Clerk, R.A., William Crookes, V.P.C.S., Sir William Robert Grove, M.A., Augustus G. Vernon Harcourt, F.C.S., Sir Joseph Dalton Hooker, C.B., K.C.S.I., D.C.L., Vice-Admiral Sir Astley Cooper Key, K.C.B., Lieut.-Gen. Sir Henry Lefroy, C.B., Lord Lindsay, P.R.A.S., Sir John Lubbock, V.P.L.S, Lord Rayleigh, M.A., Charles William Siemens, D.C.L., John Simon, C.B., D.C.L., Prof. Allen Thomson, M.D., F.R.S.E. It will be remarked that Sir Joseph Hooker has carried out his intention of retiring from the presidency.

PROF. WÜRTZ delivered his Faraday Lecture on Tuesday evening at the Royal Institution, and was entertained at dinner last night at Willis's Rooms. We hope next week to give a full account of the proceedings on both occasions.

PROF. GYLDÉN, Director of the Stockholm Observatory, has received the Cöthenius Medal of the German Leopold-Caroline Society of Science, for his important researches in astronomy.

WE understand that, at a meeting of the Professors of Queen's College, Cork, it was resolved to erect a memorial to the late Prof. Harkness, in the form of a stained glass window, in the Examination Hall of the College. It is understood that the friends of the late professor in that city and elsewhere will be invited to co-operate in raising the funds necessary for this purpose.

DR. O. FINSCH, the well-known Bremen naturalist, is about to start on a scientific tour to the Polynesian Seas; the expenses of the tour will be defrayed by the Berlin Humboldt Institution, and Dr. Finsch travels at the special request of the Berlin Academy of Sciences.

OUR Paris correspondent writes that the Werdermann electric light has attracted much attention there, and will very shortly be tried at the office of the *Temps*. The Jablochkoff light is still in operation at the Avenue de l'Opéra, but will be stopped at the end of this month, unless a new arrangement as to cost can be come to. Indeed, our correspondent informs us, unless the present price of this light is considerably modified, it is not likely to keep its place.

AMONG the latest news about the progress of electric lighting is an account of an interview with Mr. Edison, given in the *New York Sun*. His Electric Light Company proposes to light the public buildings and private residences of New York with electric lights. The electricity would be made by twenty or more engines, stationed in different parts of the city. Each station would have an engine and several electric generating agencies. He thinks that the engines will be powerful enough to furnish light to all houses within a circle of half a mile. He passes the wires right through the gas-pipes, and brings them into the houses. "All that will be necessary will be to remove the gas burners, and substitute electric burners. The light can be regulated by a screw the same as gas. He does not pretend that it will give a much better light than gas, but it will be whiter and steadier than any known light; nor does he know now that it will be cheaper than gas. To the question as to whether he could measure the amount of electricity used, Mr. Edison said he had made no attempt to discover a meter. "I know that it can be measured, but it may take some to find out how. I propose that a man pay so much for so many burners whether he uses them or not. If I find that this works an injustice why I shall try to get up a meter, but I fear it will be very hard to do it." Mr. Edison says, according to the *Sun*, that "electric generating machines could be placed upon steamboats and locomotives, and the boats and cars lighted by the action of the engines, but the instant that the machinery stopped the lights would go out." Country towns, with the use of the electric generating machines, could be lighted by water power. Any power could be used provided it was strong enough to turn the shaft of the machine with the necessary rapidity. In an article on the subject of Electric Lighting in yesterday's *Times* an account is given of an exhibition of a new electric light by the Electro-Dynamic Light Company of New York on the 29th ult. It is described as a very simple affair, consisting of a small pencil of carbon a little larger than an ordinary pin, connected by wires with an electric machine, and inclosed in a hermetically sealed glass globe, which is filled with pure nitrogen gas. The pencil of carbon is heated by the electric current to a temperature of from 30,000° to 50,000° Fahrenheit. In an atmosphere with which it cannot chemically combine the carbon is practically indestructible, and the light is therefore produced without any consumption of material. In the experiments made five lights were placed in different parts of the darkened room, and all were connected by wires with a small electric machine. In an adjoining room a simple key was placed in one of the three ordinary keyholes in one of the walls and turned a little. Two of the burners attached to a hanging chandelier in the centre of the room immediately glowed faintly, and as the key was turned still further around the glow increased until a brilliant and perfectly steady white light was obtained,

equal to the light of twelve ordinary gas jets. The key was then turned to another of the keyholes, and another of the lamps was lighted up. In the same way the fourth and fifth burners were ignited, and there resulted an exceedingly brilliant white light, yet so soft and steady that it did not pain the eyes. The lights were easily turned to any desired degree of brilliancy —from that of a mere spark to a light of six times the intensity of the common gas jet, that being the *maximum* power of the lights in use. The company asserts its ability to easily fit up lights equal to thirty gas-burners. By a very simple "switch" in the wall the current of electricity is divided and subdivided to supply any number of burners desired, the electricity reaching the switch from the generator through a single wire. The light is turned on or off or regulated to any degree merely by turning a key which operates upon the switch. The plan is similar to that proposed by Edison. The difficulty of a meter has been overcome by the invention of a meter which will record the number of burners used in any given house and the number of hours each burner is lighted.

THE Institution of Civil Engineers have, as usual, issued a circular inviting communications on a number of subjects connected with their department; for such as meet with their approval they award several valuable prizes. The circular may be obtained by applying to 25, Great George Street, Westminster.

PROF. S. P. THOMPSON lectured to an audience of 2,600 persons in the Colston Hall, Bristol, on November 8, on the Electric Light. The Jablochkoff candle and Wallace lamp were amongst the systems shown in operation. The lecture is to be repeated on the 13th inst. to the working-men of Bristol.

WE are glad to notice a little work which is being done at Winchester, and which deserves commendation as a step in the right direction by a corporation. Mr. P. S. Abraham, M.A., B.Sc., who has for two months been engaged in naming, arranging, and cataloguing the different objects in the Winchester City Museum, has sent in a report to the Committee, from which we glean the following:—The zoological portion of the museum contains some 1,700 objects, which have been labelled and placed in their proper scientific positions by Mr. Abraham. This number is made up of 70 mammalian animals, 430 birds, 50 reptiles and frogs, 80 fishes, 50 specimens of corals, sponges, &c., and about 1,000 molluscs. There are, in addition, a few specimens of articulated animals, and a small cabinet of insects. There is also a valuable collection of lichens—many from Hampshire—and comprising 227 varieties. In the mineralogical room Mr. Abraham has classified, labelled, and arranged two large cases of minerals, which now contain above 1,200 specimens, one case of rocks, with 300 specimens, and two cases of fossils containing nearly 1,300 specimens. There are, besides, large and valuable collections in various other departments, though Mr. Abraham states they are very insecurely cased. We hope the Corporation will adopt his recommendations. He observes that the museum contains an excellent nucleus of specimens. The collection could be easily improved and enlarged by a judicious curator, by the exchange of duplicate specimens, of which there are many, and by filling up gaps by purchase of the wanting representative forms. In this manner, and without very great expense, the museum might be made well worthy of the city of Winchester. The Committee conveyed to Mr. Abraham their "unanimous expression of approval at the able manner in which he has arranged, labelled, and catalogued the collection in the City Museum."

VIOLENT volcanic eruptions are reported from several of the Aleutian Isles in the North Pacific. The news was brought to Honolulu by whalers returning from the Arctic Seas through Behring's Straits. The high volcanoes upon Amukta and Tshegula sent forth gigantic columns of smoke and copious streams of lava, and the same was the case with the mountain upon Umnak, which reaches a height of 2,800 metres. On the island of Unalashka an earthquake accompanied by a tidal wave totally destroyed the village of Makushin on August 29.

A LARGE sea- and fresh-water aquarium is now in course of construction at Leipzig. It will consist of about twenty tanks, of which nine are to contain marine animals. The capacity of the tanks will vary from 350 to 800 litres.

REMARKABLE discoveries of Roman structures have recently been made at Bonn, on the Rhine. It has been found that the Castrum the Romans had established there by far exceeded in extent and importance the celebrated Saalburg near Homburg. Unfortunately the directors of the Provincial Museum of Bonn, by whose orders the excavations were begun, were not able to acquire the ground upon which the discovery was made, so that archæologists must remain satisfied with the mere fact of the discovery and the measurements taken.

NEAR the Norwegian town of Hamar, at a farm called Storhammer, some 170 silver coins have been found in the ground, none of which are dated later than the year 1530. They are all of Danish, Swedish, or Norwegian origin. At the same time two silver spoons, a gold ring, and several small silver hooks, were found. All the objects have been purchased by the Christiania Museum.

IN 1880 there will be an international exhibition of sea and river fishing-tackle at Berlin. The programme of the exhibition, which will contain no less than nine subdivisions, will shortly be sent to all interested in fisheries, both in Germany and abroad.

FROM the twenty-second annual report of the Sheffield Free Libraries and Museum we are glad to see that in the reference department a large increase has taken place in the demand for books in the class of arts and science. Considerable additions have been made to the museum.

THE *Natural History Journal*, "conducted by the Societies in Friends' Schools," for October 15 contains several interesting papers on various scientific subjects. A new feature is the illustrations, which have been made by an ingenious, simple, and inexpensive process, described in the first paper. One of these, "Societies in Friends' Schools," is the Lisburn School Association, which sends us a very favourable "Fourth Annual Report." We have also received a creditable Annual Report (the eleventh) from the Metropolitan Scientific Association, which meets at the Ward Schools, Aldersgate Street, on the fourth Tuesday in each month.

WE have received a well-arranged list of lectures to be given in connection with the Hull Literary and Philosophical Society, in which scientific subjects are given a large place.

THE *Gardener's Chronicle* publishes the following abstract from a letter recently received from Dr. Beccari, from Sumatra:—"I have very little time to spare, only to tell you of a botanical discovery which I think is of some interest. It is a gigantic Aroid, which can only be compared with the Godwinia discovered by Seemann in Nicaragua. I have no books with me, and I am not able to ascertain the genus to which it belongs, especially as I have seen it only in fruit. I believe it to be a Conophallus, and if so, I propose to name it *Conophallus titanum*. The tuber of a plant that I dug up is 1·40 m. in circumference. Two men could hardly carry it; they fell down and the tuber was broken. I will secure some more, and I hope to be able to forward them to Florence in good state. Meanwhile I send you some seeds. From this tuber, as in the genus Amorphophallus, only one leaf is produced, which in form and segments does not much differ from those of the above-named genus. But what different dimensions! The stalk at the base was 90 ctm. in girth, it was slightly attenuated

at the apex, and reached the height of 3·50 m.; its surface was smooth, of a green colour, with numerous small, nearly orbicular dots, of a white colour. The three branches into which it was divided at the top were each as large as a man's thigh, and were divided several times, forming altogether a frond not less than 3·10 m. long. The whole leaf covered an area of 15 m. in circumference. The spadix of a plant that I found in fruit had the dimensions of the stalk already described; the fruit-bearing portion was cylindrical, 75 ctm. in girth, 50 ctm. long, and was densely covered with olive-shaped fruits 35–40 mm. long and 35 mm. in diameter, of a bright red colour, each containing two seeds." This letter was addressed to the Marquis B. Corsi-Salviati, who received at the same time a number of seeds of this gigantic novelty. Many of them have germinated, so that the species is secured to European collections.

THE Giffard great captive balloon was disinflated last week without accident. The following statistics in connection with the enterprise may be interesting. The Tuileries grounds were opened to the public during 100 days, but the balloon was unable to work owing to the state of the atmosphere during 30 days. The number of ascents was 1,023, the number of passengers 34,000. The number of pioneer balloons sent up 25. During this period the sum of 840,000 francs was collected. The expenses of building the balloons, of machinery, and working, reached about 500,000 francs, so that the enterprise was a financial success.

THE *Daily News* Quebec correspondent telegraphs as follows:—"After long study and many experiments Prof. Bell has made an important discovery in connection with the telephone. It is well known that the telephone has been a comparative failure in England on account of the fatal induction generated by the contiguity of other wires. Prof. Bell has discovered simple and efficacious means whereby not only is induction prevented, but the clearness and force of the telephonic vocalisation greatly increased. Prof. Bell tells me that practical demonstration of the importance of the discovery will be given in London as soon as the necessary preliminaries are complete." We give this statement as published in the *Daily News*, though it must be received with some caution.

A NATIVE Japanese paper states that besides the two docks already existing at Yokoska, a third is to be built which will accommodate the largest ships on the Pacific. It is expected that it will be completed within three years, and the probable cost will be about 55,000*l*.

FROM Stuttgart (E. Schweizerbart'sche Verlagsbuchhandlung) is announced a second collected edition of Mr. Darwin's works in twelve volumes, with 326 woodcuts, seven photographs, twelve charts and tables, and a portrait of the author on copper-plate.

THE publishing house of Hartleben, in Vienna, to mark the seventy-fifth year of its existence, have issued a neatly-printed catalogue of all the works issued by them from 1803 to the present year. A very large proportion of these belong to the various departments of science. The catalogue contains a portrait of the founder of the house, and a sketch of its history.

FROM Mr. Murton's annual report on the Botanical and Zoological Gardens at Singapore we learn that, both botanically and zoologically, the Gardens are in a flourishing state. One of the most important sections of the garden, namely, that devoted to the cultivation of economic plants, continues to receive a large share of attention, patches of Liberian, Cape Coast, and Arabian coffee have been planted, as well as cocoa, China and Assam tea, and ipecacuanha. *Castilloa elastica* and *Manihot Glaziovii*, both valuable rubber, or caoutchouc yielding plants, natives of South America, as well as the Sarsaparilla, Alligator pear (*Persea gratissima*), New Zealand Flax (*Phormium tenax*), Cubeb (*Piper Cubeba*), Camphor (*Camphora officinarum*), Allspice (*Eugenia Pimenta*), and many others, have been introduced. The Liberian coffee plants, sent to Larut in 1875, are reported to be making good growth with large healthy foliage, forming a great contrast to the Arabian coffee growing beside it. The Salt Bush, which is referred to two species of *Rhagodia*, namely, *R. hastata* and *R. parabolica*, has been introduced into Singapore. Both species are described as possessing wholesome and nutritious qualities, and are much relished by stock. The cultivation of the plants is said to be very easy, and in consequence of the rapidity with which, when protected from stock, they grow into large and handsome shrubs, together with their capability of resisting both heat and drought, are strongly recommended for cultivation. Besides the use as fodder, in a fresh state, the plants might also be advantageously given to sheep and cattle after being cut and dried, or in conjunction with other foods. In Singapore the plants seem better able to resist heat and drought than prolonged wet weather, but it is anticipated that, when they become well established, they will survive the effects of wet weather better. Mr. Murton states that the object that will be kept steadily in view in the working of the new economic garden is the introduction of new plants of economic value, and thoroughly testing their capabilities of production in Singapore before recommending them for general cultivation, while it will also afford an opportunity to intending planters in the Malay Peninsula of seeing the various plants adapted for their cultivation, and the amount of success, or otherwise, attending each operation. In the Zoological department little change has been affected to call for note.

THE additions to the Zoological Society's Gardens during the past week include two Arabian Baboons (*Cynocephalus hamadryas*), from Arabia, presented by Mr. C. Wood; two Squirrel-like Phalangers (*Belideus sciureus*) from Australia, presented by Mr. E. S. Waller; two Hooded Crows (*Corvus cornix*), European, presented by Capt. F. H. Salvin; a Burchell's Zebra (*Equus burchelli*) from South Africa, a Yellow-Shouldered Amazon (*Chrysotes ochroptera*), a Blue and Yellow Macaw (*Ara macaco*) from South America, a Dalmatian Dog (*Canis familiaris*), a Passerine Owl (*Glaucidium passerinum*); two Variegated Sheldrakes (*Tadorna variegata*) from New Zealand, six Summer Ducks (*Aix sponsa*) from North America, two Scarlet Tanagers (*Ramphocœlus brasiliensis*) from Brazil, two Grenadier Weaver Birds (*Euplectes onyx*) from West Africa, two Java Sparrows (*Padda oryzivora*) from Java, two Domestic Fowls (*Gallus domesticus*) from Japan, deposited; a Nisnas Monkey (*Cercopithecus pyrrhonotus*) from Nubia, a Red-Fronted Lemur (*Lemur rufifrons*) from Madagascar, a Mantchurian Deer (*Cervus mantchuricus*) from Japan, an American Tantalus (*Tantalus loculator*) from South America, purchased.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

AN influential meeting was held last week in Liverpool to consider the report of a committee appointed at a previous meeting to draw up a scheme for the establishment of a college for higher education in Liverpool. The committee have arrived at the following conclusion: that the most appropriate name will be "University College, Liverpool," unless the name of a founder or large benefactor be adopted. The smallest staff consistent with the objects should be composed of at least seven professors and two lecturers, allotted as follows:—Professorships—Mathematics and experimental physics; classical literature and history; engineering, practical mechanics, and steam; logic, mental and moral philosophy, and political economy; modern literature and history; chemistry, natural history (including botany, zoology, and geology). Lectureships—Jurisprudence and law; physiology. The stipend of each professor should be reckoned at 300*l*. per annum (exclusive of a share of

the fees), which is about the average of the stipends in the colleges recently established; and that of each lecturer at 150*l.* per annum. A further sum will be required for class expenses and for the general expenses of the college. A college consisting of the staff recommended would therefore require a permanent income of at least 3,000*l.* per annnm, necessitating a capital of 75,000*l.* This estimate does not include the cost of erecting any building for the purposes of the college, or the rent which might have to be paid for the necessary accommodation pending such erection. The committee suggest the desirability of deferring for the present the question of the government of the college, and they recommend that the management be placed in the meantime in the hands of a committee to be appointed by the adjourned town's meeting. The report was adopted and a committee appointed to carry out its objects.

A MEETING was held on Monday, in the City, for the purpose of formally constituting the "City and Guilds of London Institute for the Advancement of Technical Education." The meeting was, in fact, the first held by the Board of Governors which the provisional committee of the Guilds had recommended should be constituted as the supreme governing body of the new institute. This body consists of representatives from the subscribing Livery Companies, nominees from the Court of Common Council, the Lord Mayor, and other City officials, with a president and twelve vice-presidents. The amount of available income already promised is over 12,000*l.*, but it is anticipated that as soon as any actual progress is made in the work, contributions will be given by the companies who have not yet joined in the scheme. The proposals which the committee have before them include the establishment in London of a central technical school, the establishment and assistance of evening classes, trade schools, &c., and the development of a system of technical examinations such as that now carried on by the Society of Arts. All these proposals were made in the provisional committee's reporr, and it was proposed to carry them all into execution as soon as sufficient funds were obtained. It was stated at the meeting on Monday that the Commissioners of the 1851 Exhibition were proposing to erect a building at South Kensington in which would be included a technical school, and it was, therefore, understood that either some arrangement would be come to with them or the execution of the proposals connected with the London school would be deferred till it was definitely known what direction the action of the Commissioners would be likely to take. It may be assumed, therefore, that the proposals of the executive committee will embody the other recommendations of the provisional committee, and will include a detailed scheme for carrying them out.

THE New South Wales correspondent of the *Colonies* states that, in consideration of the necessity which is now felt] for extending the curriculum of Sydney University and augmenting its teaching powers, the Colonial Government have consented to ask Parliament for an additional annual grant of 5,000*l.* This will enable the Senate to make the following additions to the present course of study:—Mental philosophy, law, history, and English literature; (2) all the education necessary for the medical profession; (3) a complete course of natural philosophy, coupled with mechanics and engineering; (4) the addition of organic chemistry and metallurgy to the chemical school; and (5) biology, including animal and vegetable physiology. The Senate will also be in a position to establish a faculty of science, and to confer the degrees of Bachelor and Doctor of Science, and also degrees in medicine, on those who have received their education in Sydney.

WE have received a "Calendar" of Anderson's College, Glasgow, containing much information as to the founder and the curriculum of that useful institution. It shows that a very complete and thorough education may be obtained there at a very moderate cost.

SOCIETIES AND ACADEMIES

LONDON

Zoological Society, November 5.—Mr. A. Grote, vice-president in the chair.—A communication received from Mr. J. H. Gurney, F.Z.S., contained a memorandum from the late Mr. E. C. Buxton, stating that *Asturinula monogrammica*, observed on the Eastern Coast of Africa, had a song which was heard morning and evening.—An extract was read from a letter addressed to the Secretary by Dr. A. B. Meyer, C.M.Z.S., respecting a supposed new bird of paradise, obtained on the West Coast of New Guinea.—An extract was read from a letter addressed to the Marquis of Tweeddale by Mr. A. H. Everett, stating that the anoa of Celebes (*Anoa depressicorms*), or an allied species, was found in the Island of Mindoro, Philippines.—Prof. Newton, F.R.S., exhibited and made remarks on a supposed hybrid between the red grouse and ptarmigan, lately shot in Sutherland by Capt. Houston.—A communication was read from Mr. R. Bowdler Sharpe, F.Z.S., containing a description of a new species of *Indicator*, with remarks on other species of the genus.—A second paper by Mr. Sharpe contained a note on *Pœoptera lugubris*.—A communication was read from Mr. G. B. Sowerby, Jun., wherein he gave the descriptions of ten new species of shells from various localities.—Mr. A. G. Butler, F.Z.S., read a paper in which he gave the description of a remarkable new spider, obtained in Madagascar by the Rev. W. D. Cowan, for which the name of *Cœrostris avernalis* was proposed.—A communication was read from Lt.-Col. R. H. Beddome, C.M.Z.S., containlng the description of six supposed new species of snakes of the genus *Silybura*, family Uropeltidæ, from the Peninsula of India.—A communication was read from Mr. Edgar A. Smith, F.Z.S., containing the description of a collection of marine shells, made by Capt. L. W. Wilmer, in the Andaman Islands.—Mr. F. Moore, F.Z.S., communicated a list of the lepidopterous insects collected by Mr. Ossian Limborg in Upper Tenasserim, with descriptions of new species.—Mr. George French Angas, C.M.Z.S., gave the descriptions of six species of bivalve shells in the collection of Mr. Sylvanus Hanley, F.L.S., and of a *Helix* from the Solomon Islands. Mr. Angas also read descriptions of ten species of Marine Shells from the Province of South Australia. Mr. Angas likewise read a list of additional species of marine mollusca to be included in the fauna of the Province of South Australia, with notes on their habitats and local distribution, in continuation of former papers on this subject.—Dr. G. E. Dobson read a note on *Myxopoda aurita*, a new form of chiroptera from Madagascar, remarkable for possessing suctorial disks, as in *Thryroptera*. Mr. Dobson also gave descriptions of some new or rare species of bats based on specimens in the Museum of Natural History of Paris. To the new species the following names were given:—*Pteropus germaini* from New Caledonia, *Cephalotes minor* from New Guinea, *Emballonura raffrayana* from Gibolo, and *Schizostoma brachyote* from Cayenne.

CAMBRIDGE

Philosophical Society, October 28.—Annual General Meeting, Prof. Liveing, president, in the chair.—The following were elected Officers and new Members of Council for the ensuing year.—President, Prof. Liveing; Vice-Presidents, Prof. Stokes, Prof. Newton, and Prof. Clerk Maxwell. Treasurer, Dr. J. B. Pearson. Secretaries, Mr. J. W. Clark, Mr. Coutts Trotter, and Mr. J. W. L. Glaisher. New Members of Council, Prof. Humphrey, Prof. Cayley, Mr. W. M. Hicks.—Prof Cayley made a communication to the Society upon the transformation of co-ordinates. He investigated the formulæ for the transformation between two sets of oblique co-ordinates in three dimensions, which, when presented in the notation of matrices, assumed a very elegant form. The paper also contained developments relating to certain expressions that were involved in the transformation.—Mr. J. W. L. Glaisher made a communication to the Society on Henry Goodwyn's "Tabular Series of Decimal Quotients" and "Table of Circles" (London, 1823). The first contains the value, to eight decimal places, of every vulgar fraction, whose numerator and denominator, when the fraction is expressed in its lowest terms, do not exceed 1000. This table, in which the fractions are arranged in order of magnitude, was intended to extend to $\frac{1}{2}$, but only the first part, which ends at $\frac{99}{991}$, was published. The "Table of Circles" contains all the complete periods corresponding to the denominators, prime to 10, up to 1024. The object of the tables was the conversion of vulgar fractions into decimals, the complete quotients being shown. In the first table the fractions are arranged in order of magnitude, and Mr. Goodwyn was thus led to a remarkable theorem, viz., that if all the fractions in their lowest terms having their numerators and denominators both not exceeding a given quantity n be arranged in order of magnitude, then each fraction is equal to the fraction formed by adding together the two numerators and the two denominators

of the fractions on each side of it. Thus if $n=5$, the fractions are $\frac{1}{5}$, $\frac{1}{4}$, $\frac{1}{3}$, $\frac{2}{5}$, $\frac{1}{2}$, $\frac{3}{5}$, $\frac{2}{3}$, $\frac{3}{4}$ $\frac{4}{5}$, and, for example, $\frac{1}{3}=\frac{1+2}{4+5}$; also the difference between any two consecutive fractions is equal to unity divided by the product of their denominators. These properties, discovered by Mr. Goodwyn, were afterwards proved by Cauchy. Mr. Glaisher pointed out the great convenience of the arrangement of the periods in Goodwyn's tables, and exhibited a table showing the number of periods corresponding to every denominator up to 1000, and the number of figures in each period. This table was obtained by actual counting from Goodwyn, and in every instance the product of the number of figures in each period and the number of periods was found to be equal to the number of numbers less than the denominator and prime to it, as should be the case. After alluding to other similar tables, and to tables by Gauss, Reuschle, Desmarest, Shanks, &c., reference was made to the fact discovered by Desmarest that the number of figures in the period of the reciprocal of 487^2 is the same as the number of figures in the period of the reciprocal of 487, or in other words, $10^{486}\equiv 1$ (mod 487^2). In vol. iii. of *Crelle* Abel proposed the query, "Can $x^{\mu-1}\equiv 1$ (mod μ^2), if μ be a prime and x less than μ?" Jacobi replied and showed that $3^{10}\equiv 1$ (mod 11^2), $14^{28}\equiv 1$ (mod 29^2) and $18^{36}\equiv 1$ (mod 37^2). The case found by Desmarest is the only one known in which the conditions of Abel's question are satisfied for $x=10$; in fact we have $10^2\equiv 1$ (mod 3^2) and $10^{486}\equiv 1$ (mod 487^2), and there is no other known case in which $10^{p-1}\equiv 1$ (mod p^2), p being a prime, although there is no reason to suppose that such cases do not exist, and that there is not some value of p for which $10^{p-1}\equiv 1$ (mod p^3). Desmarest has verified that for values of p less than 1000 the congruence $10^{p-1}\equiv 1$ (mod p^2) is only satisfied for $p=3$ and $p=487$. Mr. Glaisher also exhibited the first fourteen printed pages of the factor table for the fourth million, an account of the construction of which was communicated to the Society on February 11, 1878.

PARIS

Academy of Sciences, November 4.—M. Fizeau in the chair.—The following papers were read:—Researches on the stability of the ground and of the vertical of Paris Observatory, by M. Mouchez. M. Wolf is occupied with the former question. M. Gaillot has been studying the latitude given at different epochs. The variations of a few tenths of a second in this, at different times of the year, are thought due to the influence of temperature either on the instruments, or (rather) on the astronomical refractions, whose coefficient has not yet been adequately determined; or they may be due to a systematic error of the declination of stars distributed regularly over the twenty-four hours of right ascension, these hypotheses being more admissible than that of a variation of the vertical.—On the reciprocal displacements between oxygen, sulphur, and halogen elements, combined with hydrogen, by M. Berthelot.—Reciprocal displacements between weak acids, by the same. Two weak acids opposed to each other divide the base, the division being regulated by the state of partial decomposition of the two salts dissolved, which depends both on the proportion of water and on that of the corresponding acid.—On the reaction between mercury and hydrochloric gas, by M. Berthelot. 13·5 gr. of mercury and 48 cub. ctm. of pure hydrochloric gas put in a very resistant sealed glass tube and heated to the highest possible temperature for an hour, yielded a little over 1 cub. ctm. of hydrogen, indicating decomposition of about one-twentieth of the hydrochloric gas.—Preliminary note on the compound nature of the chemical elements, by Mr. Lockyer. Besides calcium, several substances considered as elements are compounds.—On the native iron of Greenland and the basalt containing it, by Prof. Lawrence Smith. He gives an analysis of a memoir on the subject. He is convinced the iron is of terrestrial origin, and in many cases so intimately united with basalt that the felspathic and other crystals of the latter penetrate the iron particles. The iron is probably a secondary product formed by decomposing action of beds of lignite and other organic matters which the immense basaltic dykes have penetrated.—On a universal law relative to the dilatation of bodies, by M. Levy, a reply to objections.—On the maturation of the grain of ergot. The substance which plays the part of sugar in this grain, the author finds identical with *synanthrose*, the saccharine matter found in *Synanthereæ*, and more especially in Jerusalem artichokes. It is the only saccharine matter present, and it diminishes rapidly in proportion as maturation advances (but does not wholly disappear), being replaced by starch, formed doubtless at its expense. Wheat, oats, barley, and maize, do not contain synanthrose, but cane-sugar. Thus one may readily detect in flour the fraudulent addition of ergot flour.—On the dangers of the use of methylic alcohol in industry, by M. Poincaré. Animals kept eight to sixteen months in air, ever renewed, but charged with vapours of methylic alcohol, undergo hypertrophy and fatty degeneration of the liver, a like alteration of the muscular fibres of the heart, epithelial cells, uriniferous tubes, and the lung cells, also congestion of the nervous centres, &c.—M. Gelis stated that, owing to large demand, he proposed manufacturing 200,000 kilogrammes of sulphocarbonate of potassium (for phylloxera) for the coming year, and he desired the Academy to obtain from the railway companies reduced prices of transport.—Mr. Warton presented a marine compass with nickel needles.—On the direction of the vertical of Paris Observatory, by M. Gaillot. See first paper.—On a simple property, characterising the mode of distribution of weight of a solid, placed on an elastic horizontal ground, between different parts of its base, when the latter is a horizontal ellipse, by M. Boussinesq.—On certain ordinate series with reference to powers of a variable, by M. Appell.—On the rectification of a class of curves of the fourth order, by M. Darboux.—On an iodised derivative of camphor, by M. Aller. The formula is $C_{10}H_{15}IO$.—On the region of the solar spectrum indispensable to vegetable life, by M. Bert. The part thus necessary to life is that between the lines B and C; but it is not sufficient; for behind red glass plants may live, indeed, long, but they get elongated to excess and slender, with narrow and little-coloured foliar limbs; the blue and violet rays rectify this.—On relations presented by phenomena of motion proper to reproductive organs of some phanerogams with cross and direct fertilisation, by M. Hæckel. Motion provoked in both male and female organs seems to serve physiologically for cross fertilisation, while spontaneous motion assumes direct fertilisation in plants which are not sensibly profited by crossing. The former oftener characterises the more highly-organised plants, the latter seems proper to the less highly-organised.—Reproduction of felspars by fusion and prolonged maintenance at a temperature near that of fusion, by MM. Fouqué and Levy. The experiments here described were on oligoclase, labrador, and albite.—On two specimens of natural crystals of sulphate of magnesia (epsomite) of remarkable dimensions, by M. De Rouville.

THURSDAY, NOVEMBER 21, 1878

MATHEMATICS AT CAMBRIDGE.

THE Cambridge Examination for Mathematical Honours has for a long time enjoyed a high reputation, especially among Cambridge men, who have been accustomed to point to it as the model of what an examination should be. The credit thus claimed has been in past times more or less deserved, but to what extent it is so now is a question on which there may be variety of opinion. Like every other institution, the practical usefulness of which depends upon the ease with which it can adjust itself to external conditions, the Tripos examination must undergo changes to meet corresponding changes from the outside; and there may come a time when the external conditions operate so powerfully that mere modifications are insufficient, and when the changes made must be both radical and extensive. The old Tripos system has recently been put to a severe strain, and it is admitted on all hands that the result has proved unsatisfactory. We propose to inquire into the causes which have brought this about, and to discuss the measures by which it is hoped the evil will be met.

It may be laid down as a fundamental axiom that a university honours examination should be in harmony with the studies of the candidates, and that it should be reasonable in its demands upon them. What the very best students may be expected to answer after faithful work during their undergraduate course should clearly be taken as a guide in fixing a superior limit to the number and difficulty of the questions. Nor should this estimate be pitched too high, because there are other subjects of interest and study besides mathematics, in which it is desirable that even the best of young mathematicians should engage, and an education based on mathematics alone must necessarily be defective.

If we accept these propositions we must admit that the estimate of what is reasonable towards the candidates was very different fifty years ago to what it is now. One cannot help looking back with regretful eyes on the Tripos questions of that time, so remarkable for their simplicity and elegance, as well as for the happy appreciation of the degree of difficulty such questions should possess. The questions of more recent times, although they are often to be admired from an æsthetic point of view, are in many instances far beyond the reach of any but the very best men, and may be described as being somewhat too difficult and elaborate.

There are obvious reasons why, as time goes on, the questions should become more difficult; still it would be interesting to trace the changes over some considerable period, so as to be able to explain how the Tripos examination has reached its present form. The changes must have been of a gradual character, because the traditions and customs of the examination have been faithfully transmitted from one set of examiners to the next. One can see, however, that if any particular person were to examine often, as has occasionally happened, or if several persons of like tastes were to examine together, we should find the questions displaying a particular bias. When this should occur, the studies of the candidates would receive the same bias, and particular branches of mathematics would thus be pushed for a time into undue importance. So much was this the case about the year 1864 that Sir G. Airy, when delivering the Rede lecture in the Senate House, went out of his way to denounce the excessive attention given in the University to certain branches of pure mathematics.

We can thus imagine the Tripos examination based upon the traditions of its predecessors, yet continuing to grow both in extent and difficulty, and with some of its features perhaps somewhat exaggerated. In 1873 a great change had to be made. The University, feeling it was not creditable to it that so little encouragement should be given to the higher branches, and especially to the great modern subjects of mathematical physics, determined that those subjects should be introduced into the Tripos examination. The additions thus made, besides considerable extensions in the subjects already existing, included, amongst others, Elliptic Functions, Electricity, Magnetism, and Heat.

It was thought that in thus extending the examination the students would have a choice of subjects, and that their course of study would thereby be rendered more interesting than it was before. It was certainly never intended that the burdens under which the Tripos candidate was already staggering, should be increased upon him. But how were these changes met on the part of the students and on the part of the teachers? The immediate result seemed to be that the best candidates attempted to know something of all the subjects. The examiners in 1874 were careful to watch for indications as to whether the candidates had devoted themselves to special groups, but they reported that there was no evidence to that effect. The University thereupon passed a Grace enacting that the number of questions in the higher subjects should be increased, the object being to supply a sufficient variety so that a candidate who had confined his studies to a limited group might reasonably expect plenty to occupy him in the examination. This provision has continued operative down to the present time, but it does not appear to have produced the salutary effect intended. There is much reason to fear that the best candidates still push their way through most of the subjects, whilst the next best struggle as far in the same direction as they can.

There is then a well-defined evil to be remedied. For no one can deem it a good education where the student is carried, necessarily with rapidity, over a variety of subjects, many of which he must therefore very imperfectly comprehend. What changes in the examination are proposed to the University as a remedy we will presently describe. Meanwhile let us glance at the position of the teachers in their relation to the new state of affairs.

It must be admitted that the great changes made in 1873 found the college lecturers unprepared. There were only one or two of them who ventured to expound the new subjects to college classes. The students were therefore compelled to depend upon the private tutors, and thenceforth the selection of groups became difficult, if not impracticable. The fact we have just mentioned was, in truth, a misfortune in more ways than one. For the new subjects, and, indeed, the higher subjects generally

admit of being really well taught only by men specially devoted to them, which clearly the private tutors as a class could not very well be. The higher subjects must accordingly for some time be taught in an uncertain way, and meanwhile we are deprived of the evidence, which would have been useful in the present emergency, as to how the Cambridge system would work if these subjects were completely in the hands of the lecturers, as they should be.

As between college lecturers and private tutors we have some reason to hope that one effect of the introduction of the new subjects will be that the former will rise in importance and the latter will, at least relatively, decline. We wish to write nothing but good of the private tutors personally, but if that result should really take place we should regard it as a decided boon. There may be some cases in which private tuition may have merits of its own, but for the ordinary student to have a private tutor perpetually at his elbow when he meets with a difficulty is to give him the worst possible education. In like manner we do not admire the system of more than paternal supervision practised by many of the college tutors over their pupils, the natural effect of which is that the pupil is not allowed to act or to think for himself. He is perpetually asking and getting advice about very trifling matters, and receives a great amount of what is called individual attention on a variety of subjects. But though he may thus gain a little knowledge, if he ultimately learns habits of self-reliance he learns them from other sources.

If the system of private tuition could be done away with, and if more vigour could be instilled into the collegiate system of lecturing, so that complete and adequate courses of lectures could be given, there would be a healthier tone and spirit in the studies of the University, and we are convinced the students would learn more and learn better. In proof of this we may state that the most successful of the private tutors in mathematics really do what ought to be the work of the college lecturer; that is, they deliver lectures to their classes and examine written work for them. We may also state that in the department of classical studies most of the students depend solely upon the college lectures.

We have made these remarks because it seems to us that the Tripos examination is only one phase of the broader question of the whole system of mathematical teaching. Certain proposals will to-day be made to the University, and if these be carried the scheme of college lectures will have to be remodelled: if at the same time a new spirit and energy could be infused into them, it would be a good thing for Cambridge teaching.

The proposed alterations in the examination may be briefly described as follows:—The subjects are in the first place thrown into two grand divisions. On the one side there are what may be called the easier subjects, covering all the ground which a moderately good candidate, whether his tastes incline him towards analysis or physics, may be expected to take up. On the other side there are the higher subjects of pure mathematics and physics. It is proposed that those two divisions should constitute the subjects of two distinct examinations.

The examination in the first division will, as regards class lists, take the place of the present Tripos, that is, the results will be given in the old form of Wranglers, Senior Optimes, and Junior Optimes, arranged in order of merit. This examination will take place in the June of the third year of residence, and only the Wranglers will be permitted to take up the second examination.

The subjects of the second examination which will take place in the following January are subdivided into four groups, and the results upon them will be given in classes, the names in each class being this time arranged in alphabetical order. It will be possible to attain a first class by doing well in one or two groups.

Those who bear unqualified hostility to competitive examinations, especially in their intensified form, when they are followed by an order of merit, will probably be satisfied for the present, hoping that at some future time they will succeed in abolishing the order of merit entirely. There are others who approve of the proposed changes, and who yet think that when confined within reasonable bounds such competitions can do no harm and may do good. Undergraduate human nature being as it is, a good contest, even such as can be had in a Tripos examination, is rather enjoyable than otherwise, and brings out qualities which are worth reckoning for something. It is also a good thing that an undergraduate should learn to have a piece of hard work well done in a given time. What has to be seen to is that the competition does not react injuriously on the course of study. There are many reasons which commend the proposed changes in that connection, and to one or two of these we will now advert.

In the first place, the higher subjects are not suitable for purposes of examination, because the questions which are likely to be put on them require long work and probably much reflection. It is good, therefore, not only that these subjects should be studied leisurely, but that the element of hurry should be as far as possible excluded from an examination upon them. It is true that the last remark will apply also to the lower subjects, but we are to consider that the latter subjects which usually consist of a few simple principles, admitting of an almost infinite variety of simple applications, are in a measure the tools of the mathematician who ought to be well skilled and expert in their use.

Again, if there is to be strict competition it is as well that the area should be narrowed and that the combatants should meet one another on common ground. In the present state of things that cannot be, but under the proposed system it will be possible for a clever lad who has read but little when he enters the University, to hold his own against a competitor, his inferior, who does not begin his undergraduate course till he has been pushed, or has plodded on a good way towards his mathematical degree.

The opponents of the proposed changes affirm that the Tripos will lose its prestige, and that the students under the new system will entirely neglect the second examination. It seems sufficient, in answer to the first of these objections, to point out that the first examination will not be so insignificant either in extent or difficulty, as not to compare in those respects with the Tripos examination of forty or fifty years ago. And as to the best students neglecting the second part, that is a circumstance which seems very unlikely to occur, but the colleges will have the matter in their own hands, and it is to be expected they would be patriotic enough to refuse their fellowships and certainly

their lectureships to students who had not distinguished themselves in both parts.

It is impossible to touch on all the points which suggest themselves in connection with this question, but we may point out in conclusion that the examination in Cambridge has to adapt itself to two classes of candidates, viz.: There is the class who may be called professed mathematicians, because they spend their lives in cultivating mathematical science and in teaching it to others, and there is the class who abandon their mathematics as soon as their undergraduate course has terminated. Of the former class we believe that their tastes and the necessities of their position will alike carry them beyond the subjects of the first examination. In the case of the second class, which is a large one, it is undoubtedly a wise thing to restrict their studies within the limits of the easier subjects. For under the present system, in their eagerness to secure good places they attempt subjects which are either beyond their powers or their opportunities, and so fail to gain the advantages which a strict mathematical training is supposed to afford.

"CRAM" BOOKS

Notes on Physiology, for the Use of Students Preparing for Examination. By Henry Ashby, M.B. (London: Longmans, Green and Co., 1878.)

THIS book, being a fairly creditable and careful specimen of its kind, seems to offer a fitting opportunity for denouncing the whole class of "cram" books of which it is a member. It purports to be notes on physiology, compiled originally, while the author was a demonstrator in the Liverpool School of Medicine, for the use of those students of the school who were preparing for the primary examination of the College of Surgeons; and it is confessedly based upon Foster's "Physiology" and the two chief anatomical text-books used in England. It is a small 18mo of about 230 pages, clearly printed in a large type, and it contains a number of condensed and dogmatic statements in all departments of physiology. It is, we rejoice to be able to say, written perspicuously and compiled with evident care. Most of what Mr. Ashby has read in Foster he has accurately digested and dogmatised. But though he has thus almost disarmed criticism as to his particular book, the book still remains infected with the vices of its class; it is a delusion and a snare to the student; and we heartily wish Mr. Ashby's talents had found a worthier object for their exercise. "Notes" are undoubtedly of the greatest value to a student—nay, they are indispensable, if he is to acquire a large view of his subject; but they are only valuable when the student has compiled them himself from the larger text-books, or, better still, from original memoirs, or when he has seen them digested and set down, so to speak, before his eyes by his teacher. Each of the sentences in his book Mr. Ashby doubtless could and would make the text of a lucid explanation in his lectures or demonstrations. He would lay before his hearers the different views of observers on different physiological questions, as he had learnt them, and, balancing the evidence, he would abstract for them a trustworthy judgment in a careful and concise statement: and the student who took down his notes, on re-reading them, would have the whole discussion refreshed in his mind with more or less vividness—would, in fact, have almost all the benefit of condensing the notes for himself. But when these concise statements or formulæ are put into the hands of students who have not been thus prepared for them, the case is wholly different. Aladdin has the lamp, indeed, but he can conjure up no powerful genii with it.

But if this were all we might be content to let books like this sink to their own level; their inutility would lead to their speedy death. But while the good student would never for a moment think of reading notes that he had not made himself, or if he did read those of another, would quickly find out the cause of their uselessness to any one but their author, the bad student is misled to believe that 230 small pages of fair-sized type contain the whole of the physiology that he needs; he looks through the list of contents and finds set down there almost every physiological fact and problem of which he has ever heard, and he naturally concludes that he has only to equip himself with this little book in order to cope with his examiner.

Mr. Ashby's book, admirable for the purposes of his own students, is useless or worse than useless to the students of any other teacher; published to the world, it is like a creature in an improper medium, and we are constrained to wish that, with all similar books, it may quickly meet the usual fate of creatures so circumstanced.

After this we need not say much about the book itself. On the whole it is well done. The histological sections are decidedly the weakest. The "ossification of bone" (p. 29), and the "development of tooth" (p. 107) might as well have been omitted altogether, as put in so meagrely. The extremely important histological researches of Heidenhain on the pancreas seem to be ignored on p. 16, where "probability" only is allowed to the elaborating functions of glandular epithelia. The pigment layer of the eye on p. 17 is assigned to the choroid coat instead of to the retina, and again on p. 194. No nucleus is given to striated muscular fibres on p. 81. On p. 179 Prof. Ferrier's name is put down at the end of a paragraph as if he were the prime authority for certain facts regarding the *corpora quadrigemina*, which we rather owe to Flourens, Longet, and Goltz. These errors are not of vital importance, and some of them have probably been due to inadvertence. But there are two more mistakes which are of greater weight, and show the danger of mere book-making. On p. 34, where the properties of muscle are discussed, we find that "On contraction . . . O is absorbed and CO_2 . . . given off." This is left unexplained here and in the rest of the book. What Mr. Ashby doubtless meant was that during contraction more arterial blood passes into muscle, and more O is taken up than during rest, while CO_2 is at the same time emitted; but, in the above unguarded way of statement, the fundamental fact of the independence of the actual absorption of O and disengagement of CO_2—a fact of the utmost moment in our conceptions of muscular work—would seem to be passed over. Again, on p. 168, under nervous conductivity, we have the curious statement that "the axis-cylinder probably conducts the impression, *the medullary sheath acting as a sort of insulator to prevent the currents from becoming mixed and confused*"—a physical explanation which no physiologist would now for a moment think of offering.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Divisibility of the Electric Light

THE English and American periodicals devoted to electrical science now announce, "on authority," that the electric light discovered by Edison is a light by incandescence. If this be true there is nothing new or startling either in the discovery of the light or of its divisibility. Lighting by incandescence has been studied for a long time; indeed, it has been studied much more thoroughly than any other kind of electric lighting. Thirty-three years ago a method of producing and sub-dividing the light was patented in England by a Mr. King. The light was produced by heating to white heat in a vacuum, by means of the electric current, either platinum or carbons; and, the specification adds, "when the current is of sufficient intensity, two or a larger number of lights may be placed in the same circuit." For some years after this discovery several improvements on King's invention were patented in America, France, and England; "but," says M. Fontaine, "none of these appear more complete, more explicit, and more practicable than King's; it is, then, useless to continue our nomenclature." The principle of lighting by incandescence, although not neglected or forgotten, seems to have made but little progress until 1871, when M. Lodyguine showed an experiment in the Admiralty Dockyard in St. Petersburg, when he divided the circuit into no less than two hundred lights. This naturally made a great sensation at the time—as great a sensation as that caused by Mr. Edison's telegram of the 7th ult. The Academy of Science awarded to M. Lodyguine the large Lomonossow prize of 50,000 roubles. A company was formed in St. Petersburg with a capital of 200,000 roubles, and the excitement in Europe was then almost as great as has been witnessed in England lately. It was soon found, however, that Lodyguine's discoveries, like those of his predecessors in the same field were, after all, impracticable, and that his illimitable division of the light, however ingenious, was only a fanciful experiment. Every penny subscribed to the company referred to was lost, and Lodyguine's great discovery is now, where it was then—in his laboratory.

It has, however, been urged that these early inventors of the electric light knew only of the galvanic battery as a generator of a powerful current, and that had they known of the Gramme machine, or other dynamo- or magneto-electric machine, the results might have been different. The remark, however, only applies to King and the improvers who immediately succeeded him. The great division of the light by Lodyguine, to which reference has just been made, was in a circuit produced by two "Alliance" machines. Even, however, if such were not the case, there are at present before the world, in more or less detail, four recent inventions for the production of a divided light by incandescence. These are the inventions of M. Reynier, of M. Arnaud, of Mr. Edison, and most recent of all, M. Werdermann. From the way in which these discoveries—if they are discoveries—have been ushered into the world, it is found that great claims are made on their behalf, and there are, therefore, naturally great expectations on the part of the public in regard to them. It cannot be urged now in mitigation of the shortcomings of the incandescent light, as it has been urged in the past, that it has not had a fair trial, on the ground that the lamps in existence were imperfect in conception, and complex in construction. The lamp of M. Reynier seems admirable in its way, and if light by incandescence were to be the light of the future, the claims of this lamp would have to be very carefully considered, and, in any case, it will certainly hold an important place in all investigations into the subject. The lamp of M. Werdermann appears to be identical in principle with, and only slightly different in detail from, that of M. Reynier, and we may fully expect that these inventors will have to come to terms with each other—so much alike are their inventions. Of the details of Mr. Edison's invention—if there are any, nothing is known beyond the fact stated in the *Scientific American*, that it is a light produced from a spiral of incandescent platinum; while the reports in the American daily press show such an effervescent ignorance of the fundamental principles both of electricity and of dynamics, that no reliance whatever can be placed upon them.

Experience, then, has shown that a light by incandescence comes before us in a very questionable shape, and it is essentially a light which discourages the notion of its practical application. The question indeed may be very properly asked: How is it that light by incandescence has always proved such an utter failure? It has had a period of thirty-three years in which to develop; it has been divided into various lesser lights, numbering from two to two hundred: and it has arrested the attention and taxed the skill of the greatest electricians in the world. How is it that it is obliged to give way to light by the voltaic arc? The answer is at hand. The light by incandescence can only be obtained and divided by a great sacrifice of light and power. This is imperative from the fundamental principles of electrical science. The diminution according to the "square," and not according to simple proportion, applies to electricity just as it applies to light, heat, sound, gravitation, and other physical phenomena. Thus if a circuit be divided into two branches whose resistances are equal, a current of half the strength passes through each branch, producing at the point of resistance, not half the light, but only a quarter, because the effect follows the square of the current strength. If the current had been divided into three equal branches, in each branch only one-ninth part of the original light would be obtained, and so on; so that if an electric light of 1,000 candles were divided into ten equal lights, the result would be ten lights of ten candles each, instead of one of 1,000 candles. When this law is borne in mind, and when it is also remembered that to produce the electric light by incandescence at least one-half of the current is lost, it will easily be imagined what a wasteful light it is. Recent experiments prove this. It was recently stated, in reference to M. Werdermann's incandescent light, that he produced two lights of 320 candles each (total, 640 candles), with a prime mover of 2 horse-power; and this was considered a great result—as indeed it was for an incandescent light. But how this sinks into insignificance when compared with the results of lighting by the voltaic arc. A few days ago M. Rapieff, with two of his regulators and a small Gramme machine known as the M machine, and which M. Gramme says requires only 1½ horse-power, produced two lights, which, when carefully measured by the photometer, were found to be each equal to 1,150 candles, or a total of 2,300 candles, while with one of M. Gramme's A machines, requiring 2½ horse-power, a light of 6,000 candles can be obtained from one of M. Rapieff's regulators. Some experiments detailed in M. Fontaine's book on "Electric Lighting" gave a similar result. M. Fontaine's experiments with an incandescent light show that, under the most favourable circumstances, with a Bunsen battery of forty-eight cells, eight inches high, the diminution of the sub-divided light was so great that, where he put five lights in one circuit, he only obtained a total illuminating power of a quarter of a burner, with four lamps only three-quarters of a burner, with two lamps six-and-a-half burners, and with one lamp fifty-four burners. These numbers give the following ratio: 1, 3, 8, 26, 216, thus showing how rapidly the light diminishes when divided. With the voltaic arc, however, and with the same battery, he was able, by a Serrin lamp, to obtain a light of 105 burners.

It will be seen, then, from what has been above stated, that the production and the divisibility of the light by incandescence is a very wasteful process—so wasteful, indeed, as to render its practical application impossible for general lighting. If, therefore, all Mr. Edison has to announce to the world is that he has succeeded in dividing an incandescent light—and the announcement that such is so is made on authority—his discovery amounts to very little. Both the light and its divisibility were discovered long ago. It will easily be seen that it is not in that direction that any great practical results can be obtained. The voltaic arc supplies the only divisible light of any utility and economy, and it is in its development that any real progress must be looked for.

WILLIAM TRANT

Duplexing the Atlantic Cable

I HAVE read with surprise in your number of the 14th inst. (vol. xix. p. 38), an article, in which it is implied that the application of the duplex method of signalling to an Atlantic cable has now for the first time been successfully accomplished by Mr. Stearns.

The publication in the *Times* of Sir James Anderson's letter on "the duplex system in telegraphing," on the day after the publication of your article, was a coincidence of which I trust

you will in fairness allow me to take advantage, to prove that your article does scant justice to Mr. Stearns' predecessors in the application of the duplex system to long submarine cables, and that their success has been something more than "only partial" in the opinion of those who have employed their system.

Mr. Stearns' first success on a long cable dates from a few days ago. In February, 1876, Dr. Muirhead and myself obtained experimentally a perfect balance on the Suez-Aden cable, which, though shorter in miles, is electrically longer than either of the Anglo Company's cables from Valentia on which Mr. Stearns has worked.

In March of the same year Mr. J. Muirhead and myself duplexed the Marseilles-Malta cable, which, though only 825 miles in length, is worked by Sir W. Thomson's syphon recorder, and our system has been in commercial operation on the line ever since.

Early in 1877 Dr. Muirhead applied the system to the Aden-Bombay Cable, which is longer in miles and far longer electrically than either of the cables from Valentia, and since that time this line, as well as that from Suez to Aden, has been worked "duplex" whenever the traffic required it, to the entire satisfaction of the company.

Next, as to your remark that "Mr. Muirhead has been at work duplexing the Direct United States Cable with some prospect of success," the facts of the case are these:—

The cable, in its linear measurement, exceeds the longest Valentia cable by 543 miles; electrically it is twice as long.

It is worked with the mirror galvanometer, and not with the recorder, and these circumstances render the difficulty of obtaining a duplex balance upon it immensely greater than upon any of the other lines referred to.

Notwithstanding the difficulties mentioned, Dr. Muirhead and myself, in April last, obtained a perfectly satisfactory balance, enabling us to transmit sixteen words a minute in both directions at the same time, between Ireland and Nova Scotia, a cable distance of 2,420 nautical miles. HERBERT TAYLOR

7, Pope's Head Alley, Lombard Street

P.S.—Since writing the above my attention has been called to NATURE, vol. xv. p. 180, containing an article on this subject, in which the applications of Muirhead's system to some of the cables referred to in my letter are spoken of as being the first practical successes in submarine duplex telegraphy.

Remarkable Colour-Variation in Lizards

MR. WALLACE's observations in NATURE, vol. xix. p. 4, on a black variety of the common lizard of Capri, as met with on the neighbouring islet of Faraglioni, induces me to refer to a similar appearance in the lizards frequenting the islet of Filfla, on the southern coast of Malta. As recorded in my book, "Notes of a Naturalist in the Nile Valley and Malta," p. 80, I have stated that during a visit to Filfla I was surprised to find that all the lizards on the rock were a beautiful bronze black and so much tamer than their timider brethren on the mainland. Many individuals were so tame that they scrambled about our feet and fed on the refuse of our luncheon. I subsequently sent specimens of this variety, or rather race, to Dr. Günther, F.R.S., who pronounced them identical with the *Podarcis muralis*, so extremely plentiful in Malta and Gozo. Now although the denizens of the two latter islands present divers shades of colouring, I never observed (and I looked carefully during several years) a black or dark-coloured individual. Filfla is about 600 yards in circumference and three miles distant from Malta. It is formed of the upper miocene limestone, and marks an important fault or down-throw which runs along the coast of Malta opposite, by which, as seen in the sketches Figs. 1 and 2 of the work referred to, it appears clear that the severance took place long subsequent to the days of the pigmy elephants, hippos, giant dormice and tortoises, whose remains have been found in such abundance in the crevices of the rocks opposite Filfla. There is no verdure on this bare rock-islet, the surface of which is dark-coloured, whilst its crevices shelter the lizards and furnish abodes for the nests of Manx and cenereous shearwaters, whose docility at the breeding season is equally remarkable, both reptile and birds being like their compeers of Enoch Arden's island, "so wild that they were tame."

Probably the dark colouring is protective, and thus consorting well with the surrounding surfaces, would tend to preserve them from the harriers, buzzards, and hawks which tarry in the Maltese Islands during the spring and autumn migrations

November 11 A. LEITH ADAMS

THE remarkable case of local colour-variation in lizards communicated by Mr. A. R. Wallace to NATURE (vol. xix. p. 4), had already been investigated by Dr. Theodor Eimer, an abstract or translation of whose memoir on the subject, entitled "*Lacerta muralis cærulea*, a Contribution to the Darwinian Theory," is to be found in *Ann. and Mag. Nat. Hist.*, 1875, 4th ser., vol. xvi. p. 234. J. WOOD-MASON

54, Claverton Street, S.W., November 16

The Drought

AT the present time, when more attention is paid to the influence of meteorological phenomena upon society, it would be useful to give some information as to the bearing of the local droughts and famines on our trade and the prospect of its revival. The China and Indian trades have not yet recovered. The droughts have also affected Egypt and Morocco. In the West Indies, Guiana, Venezuela, Colombia, and Brazil they are still operative.

They act to prevent the growth of produce, and in many countries, by reducing the water-ways, they impede its shipment. The people cannot consume our imports, the transit of which is in some cases impeded. The whole of these difficulties affects the exchanges and interferes with the money market and remittances.

The severity of the crisis is abating, but we can hardly feel assured of the revival of trade in Europe and the United States till there is a complete recovery over the vast areas of producing and consuming countries.

Thus the study of meteorological phenomena and facts acquires a new value for practical men and society at large, as stated by Prof. Jevons in your last number. HYDE CLARKE

Sewerage and Drainage

IN NATURE, vol. xix. p. 1, you touch upon a most important point in sanitary engineering which I have for ten years been striving by every means in my power to press upon the public, and I therefore venture to trouble you with a few lines on the subject.

The most important argument in favour of the exclusion of storm water from sewers consists, as you say, in the liability of road detritus to form deposits on the wide flat surface of any channels large enough to convey to one point an exceptionally heavy fall of rain over the area covered by a town, and the inevitably slow course of the infinitely smaller volume of sewage flowing or stagnating in dry weather along the same channels.

When separate sewers are provided for sewage they can be made of such smaller capacity as to keep up a constant flow from the houses in which the sewage is produced, to the land upon which it is to be purified, because the volume of liquid will very nearly correspond with the water supply, and the engineer has safe data upon which to adjust his means to the desired end.

In every town there are, or were, lines of natural watercourses, and if the scavengers' work is properly done the rain-water from roofs and streets may safely be discharged into any of these by short lengths of drains, less liable to be encumbered with deposits of road detritus, and with the certainty that if such accumulations should occur, they will be perfectly harmless from the absence of sewage.

The experiments of Mr. Way with London street water have been seized upon by Mr. Baldwin Latham in order to cover his retreat from the false position unfortunately taken up by himself and most of our senior engineers in the earlier days of sanitary science, and as he knows as well as any one else that it was a grand mistake to confuse and combine *sewerage* and *drainage* in one system, I agree with you in thinking it a pity that he has not acknowledged the facts more distinctly in the recent edition of his well-known work.

The greater proportion of the impurities detected by Prof. Way in the few samples of London street water which he tested are mineral ones which would be comparatively harmless, and, in the opinion of Dr. Voelcker, the experiments must have been vitiated by some mistake. Now as the latter authority has

publicly stated this and added his opinion that no sanitary authority could possibly object to water from streets and roofs of houses, uncontaminated by sewage, being passed directly into any river, Mr. Baldwin Latham might have been expected to have investigated the subject further before adducing the one statement without the other.

There are many other arguments of a sanitary and economical nature in favour of the collection of sewage without more dilution than necessary with rain water, but I must not trespass further on your valuable space.

ALFRED S. JONES

Rayons du Crépuscule

MY father tells me that he sees this phenomenon about five times in the year on the average in this climate. But the display at 4.40 this afternoon was unusually brilliant. The morning had been very wet, and when it cleared in W.N.W. at 2.30 we noticed the clear sky to be of an unusually green tint.

Very distant cirro-stratus on the south horizon ceased to be illumined by the rosy sunlight about twelve minutes before the phenomenon became visible. The latter consisted of very bright rosy rays, in a *very clear* sky, converging near the E.N.E. horizon, the moon shining very brightly on the left of the place of apparent convergence. The sky in interspaces between these rays was of a deep blue; these interspaces being, I suppose, the shadows thrown from distant cumuli and shower-clouds, some of which could be seen upon the western horizon.

Ashby Parva, Lutterworth, November 10 ANNIE LEY

The Power of Stupefying Spiders Possessed by Wasps

WITH reference to my letter on this subject (NATURE, vol. xviii. p. 695), Mr. Arthur Nicols writes me his disbelief that the pretended taking of the poison of snakes internally as a supposed antidote or prophylactic against the bite is anything more than a juggle of those chartered charlatans, the snake-charmers of India; or that it can be so taken with impunity. Of the wasps he says: "I dare say you know that one of the mason wasps of Australia glues its egg to the inside wall of the mud nest, and always at the top, while the rest of the space is filled with spiders. The sting of this wasp is a terrible affair. I was rendered quite comatose for several hours by being stung in the knee" [which, by the way, is precisely the condition of the spiders], "and the pain was most excruciating, with aching and swelling of the inguinal and axillary glands. I don't know whether the wasp stings the spiders, but they are always in a good state of preservation, even when the egg is on the point of hatching. I never found one in the least decomposed. The nest, however, is hermetically sealed, and decomposition could hardly take place, because so very small a quantity of oxygen is inclosed within." It will be remembered that Mr. Armit remarked "a constant movement in the legs of the spiders," and that observation has been made before.

If the word "wasps" in the above heading (which is not mine) be understood to refer to any of the true vespæ (*vulgaris*, *rufa*, *britannica*, or *borealis*), I agree with Mr. Frederick Smith (NATURE, vol. xix. p. 32), that it is misleading. But the solitary insects whose habits have been referred to, have been called wasps in all the popular books of natural history with which I am acquainted; and the correctness, or incorrectness, of the English name does not affect the points brought forward. I may, perhaps, be allowed to recall that the one object for which I referred to the Athenian insect—in connection with a correspondence then going on in your columns as to the senses of insects—was the remarkable circumstance that it seems to hunt down its prey *by scent*. Mr. Armit, of Queensland, referring to that letter, asks the further question, How are the spiders stupefied, and not killed, by a sting, formidable enough in one species to endanger the life of a man? Mr. Smith's letter throws no light on either of these points.

Bregner Bournemouth HENRY CECIL

The Ayrshire Crannog

THE remarks made by Dr. Buchanan White in your last issue in regard to the supposed existence of beech and the absence of Scotch-fir in the Ayrshire Crannog will be carefully attended to. Birch and hazel, so easily recognised by the bark, are certainly in greater abundance than any other kind of wood. I shall, however, collect as many specimens as I can find and submit them to the examination of competent authorities and publish the result in due course. We have now made a large addition to our list of relics, among which I may mention the following:—three daggers (one of which has a gold band round the handle); one knife, one gouge—all these are made of metal, of which the gouge alone has been tested and found to be bronze; a polished stone celt; a clay spindle whorl partially perforated; a curious fringe-like object made of vegetable material; several implements of bone and deers'-horn; a piece of wood with carving on it; portions of a flat dish cut out of wood; a wooden scraper cut out of a trunk of a tree with the handle formed of a branch growing straight out from it—(beside this scrape about a handful of short black hair was found);—a double paddle of a canoe together with various other wooden implements. Hitherto not a single fragment of any kind of pottery has been found on the Crannog. Being merely an amateur in this kind of research, I shall be glad to receive any suggestions from experienced gentlemen as to important points that should be looked after. ROBERT MUNRO

Kilmarnock, November 16

ON THE UTILISATION OF THE AFRICAN ELEPHANT

THE *Colonies and India*, of November 2, contains a short but suggestive article under the heading "Notes," "Elephants in Cape Colony," which deserves consideration. It states that elephants are numerous in the interior of Cape Colony as well as in Central Africa, yet no one seems to have attempted to catch and tame them. The subject has already been mooted that there is a good field for their use both in Central Africa and in Cape Colony, and that they would prove a new and important method of opening up and utilising the wealth of the Colony and of furthering the explorations in Central Africa, which are now of such general interest.

It appears that a troop of wild elephants has been observed within fifty miles of Port Elizabeth—on these the attempt might first be made—and it is well known that they abound in Central Africa, where, indiscriminately slaughtered for the sake of their ivory, the destruction of these animals is so great, as at no very distant period to threaten their extinction. It seems worthy of consideration whether it would not be better to attempt to utilise them as beasts of burden, as is done in India, where they are of inestimable service to the Commissariat, the Public Works Department, the planters, and many others. The African differs from the Asiatic elephant in some points, but is equally well adapted for labour, and, there can be no doubt, would be as easily tamed and trained as his Indian congener. That this is the case is amply proved by the docile and submissive state into which the male and female African elephants now in the Regent's Park Gardens have been brought by Mr. Bartlett and their keeper, Scott. They appear to be just as obedient, intelligent, and free from vice as Indian elephants, and there is, I think, little doubt that the one species, under proper training and discipline, would be as useful in Africa as the other is in India.

There is every reason now to hope that the wealth and resources of our South African possessions will undergo development—might it not be well to revive the suggestion that the elephant should be enlisted in the good work? The importation of one or more of the numerous officers who have been trained to the work of catching and domesticating wild elephants in India with a fitting establishment, and, perhaps, a few Indian elephants to commence the work, would very soon put the value of the undertaking to the test, and probably show that a vast source of working power now unused might be made available.

It is probable that in ancient times the African elephant was domesticated, and any one who has studied the two magnificent specimens in the Society's collection in

Regent's Park, will, I think, be satisfied that they may again be so, and that in temper, docility, and working power, they would be equal, if not superior, to the Indian elephant.

Through the medium of the columns of NATURE, perhaps an impetus may be given to a matter that is certainly worthy of consideration, and may elicit further remarks from some of the Indian Keddah officers, who are practically experienced in the mode of dealing with elephants. It is, at all events, worthy of Sir Bartle Frere's consideration. J. FAYRER

SYNCHRONISED CLOCKS

RAILWAYS, among many other services which they have rendered, have made us more particular about keeping our watches and clocks in accordance with some common standard of time, and during the past few years various systems have been tried for the distribution of a standard time from a common centre—in this country Greenwich Observatory. For purposes of public life it is more important to have all the public and even private time-pieces of a country set according to one standard, than that they should show the correct local time. The latter can easily be ascertained by any one who desires it, if he can be sure of knowing the exact Greenwich time. Of all the systems that have been tried for ordinary public use, that recently organised by Messrs. Barraud and Lund, of Cornhill, seems to us to answer all the requisite conditions. We had the pleasure the other day of inspecting the arrangements made by Messrs. Barraud and Lund for the distribution of Greenwich time from Cornhill as a centre, and we are bound to say that the perseverance and ingenuity displayed deserve success, and we believe that wonderful success has been obtained. Messrs. Barraud and Lund have spared no pains and no expense to perfect their system, which, as a practical and widely useful application of science, is full of instruction.

Any system for the public service of time-signals by synchronising currents which lays claim to approximate perfection, naturally divides itself into three distinct departments; 1. The maintenance of a standard time-keeper at absolutely correct Greenwich mean time; 2. The distribution of the time at hourly intervals with the needful apparatus for testing the work done; and last but not least, the particular means adopted to enable the time currents to control or set the various clocks in circuit to true time. As to the standard adopted by Messrs. Barraud and Lund, and which is in direct communication with Greenwich, this is a mercurial regulator of the very best construction with a Graham dead-beat escapement, having the contact springs for the time-current between the dial and upper plate, the dial being pierced so as to allow free access to all parts of this mechanism without otherwise stopping or interfering with the regulator. However excellent such a time-keeper may be some error will always exist; it will have a daily rate however small, and it becomes important that this error should be corrected at least once a-day. In order that this may be effected without actually using any physical connection, Messrs. Barraud and Lund have adopted the following method:—A permanent bar-magnet about 6 inches long, is secured to the pendulum-rod, so as to vibrate about $\frac{1}{32}$ of an inch from a resistance-coil fastened to the case by a projecting bracket; a current of electricity passing through this coil, accelerates or retards the vibrations of the pendulum according as the current sent is positive or negative, and the power of the current is adjusted to give one second of influence for one hour of duration. The wires of this adjusting current are connected with a commutator, a small instrument about two inches by three-and-a-half, having three holes—that in which a plug is normally placed when no effect is required to be produced, a second marked "fast," and a third "slow," for the reception of the plug, according as the standard requires to be accelerated or retarded. In order to secure the continuance of the current for a period neither longer nor shorter than will produce the desired result, a small ordinary clock is interposed between the commutator and

FIG. 1.

the standard clock. This clock answers a double purpose; it has no hour hand, but only a minute hand, which stands normally at twelve, in which position the clock is "stopped," and no current can pass through to the resistance coil. The plug having first been placed in the "fast" or "slow" hole, as occasion may require, the

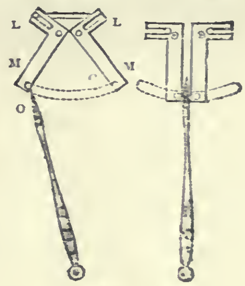

FIG. 2.

clock is set back, say one half-hour for half a second error of the standard. The mere fact of setting back this hand, *starts the small clock and closes the current* at the same moment, continuing to keep a closed current, till the hand returns to 12, when it again breaks contact and stops itself. It will thus be seen that one operation alone

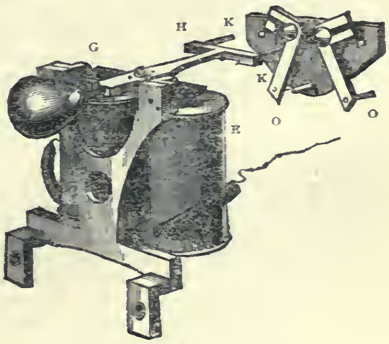

FIG. 3.

is required to set the standard, the whole action automatically ceasing the moment the standard is "to time."

The "distributor" is, in fact, a compound "relay" for twelve circuits, it having been determined to use independent batteries for each line wire in preference to split currents, as used in the chronopher at St. Martin's-le-

Grand. The appearance of this "distributor" is very much like a miniature cart-wheel, about five inches in diameter, inclosed in a circular glass-case, the spokes being the twelve contact springs and the nave a small insulated table which, when the standard automatically closes the contact springs of the time-wire at the exact sixtieth second every hour, is instantly carried down upon and closes the twelve pair of contact-springs connecting the twelve line-wires with their batteries.

Many interesting methods have been adopted for testing and other purposes of maintenance, but we have only space to mention two. One is for the purpose of warning in case of a break-down. This consists of an ordinary electric clattering bell, with a small clock attached, and also connected with the line-wire. So long as the time-currents pass regularly through this instrument the alarm-bell remains silent; but five minutes after the failure of any time signal to pass out upon its duty, the alarm-bell begins to ring violently, continuing to do so for five minutes, and then leaving a small drop indicator, showing on which line the break-down has occurred. There is only one alarm-bell, but each line requires its attendant little timepiece (which, being "synchronised" by the passing current, never can be wrong) and drop indicator. The other instrument is an alarum answering the following important purpose:—A break-down being reported, a plug is placed in a "bridge" corresponding to the number of the line, which causes a very weak current (too weak to affect any of the synchronisers) to pass out along the line for the use of the linesman when searching for the fault; this found and repaired it is important that the plug should be immediately removed: to call attention at the office in Cornhill the linesman has only to break contact at the nearest clock anywhere on the line to set the alarum going in the instrument room, when, the plug being removed, the alarum is shunted off and the line clear for work.

We now come to the chief specialty of the system of Messrs. Barraud and Lund, namely, the synchroniser. This is an automatic finger-and-thumb action, brought to bear hourly on the minute-hand, and bringing it, whether fast or slow, "to time." Each synchroniser is complete in itself, and is simply screwed behind the dial of the clock to be synchronised. It is as follows:—

Two levers carrying pins, and representing the human finger and thumb, project through a slot in the dial (Fig. 1), and either close upon the end of the minute hand itself, or upon a small block fastened to it underneath; the two levers have at their other end slots in which two pins work, projecting from the keeper of an electro-magnet, which, when magnetised at the given moment by the closing of the contact springs on the standard clock, draws the pins together, and sets the hand to time. A reference to Figs. 2 and 3 will at once make the *modus operandi* clear. E is an ordinary electro-magnet, G the keeper, carrying a bar, H, and two projecting pins, K K; these act in slots L L in the levers M M, from the ends of which project the pins O O (representing the human finger and thumb); the passage of the current draws down the keeper and bar, acts upon the levers M M, closing them upon the minute hand of the clock and setting it, whether fast or slow, to time.

The following are some of the special advantages claimed for this system:—1. That any number of clocks, few or many, of any varying sizes, can be synchronised to any agreed standard time-keeper. 2. That the mechanism is, when not in its momentary use, entirely detached from the works of the clock. 3. That it can be applied to existing clocks by simply being screwed in its place, and a narrow slit cut in the dial. 4. That any failure in the transmission of the time-current leaves the clock going in the ordinary way, to be "*set to time*" by the next completed current. 5. That the clocks are kept to time, whether having otherwise either a gaining or losing rate, even if such rate amounts to many minutes a day.

It will seen from the above description that the system owes its success not to the discovery or application of any new fact, such as that for which such eager search is now being made to secure a perfect electric light, but from the simplicity and efficiency of the synchronisers, and their adaptability to every kind and size of clock. By the simple expedient of winding the coils of all the instruments with one size wire, any number, all of varying sizes and powers, can be connected up in circuit. In the City circuit alone, which is wholly controlled by the standard at 41, Cornhill, 108 clocks on eleven different lines of an aggregate length of ten miles, and connecting over eighty different establishments, are efficiently kept to true time. Many more, we believe, are kept to time, not only in other widely distant parts of London, but in various parts of the country; for the latter purpose Messrs. Barraud and Lund have a contract with the Postal Telegraph Department for the delivery of time currents at certain hours each day. There is now no reason why all our public clocks at least should not be included within the correcting power of this system, and lead us astray no longer.

THE TELEPHONE, ITS HISTORY AND ITS RECENT IMPROVEMENTS[1]

III.

The Carbon Telephone

IN the columns of this journal (NATURE, vol. xvii. p. 512) the present writer remarked in the early part of the year "that it was unlikely the telephone of the future would employ the voice to generate the driving power, as it does in the magneto-telephone, but only to modulate the flow of a current obtained by coarser means. It is in this direction that Mr. Edison is working, and his practical triumphs in the past are the earnest of success to those excellent telephonic investigations wherein he has already won an enduring fame." Since those words were written Mr. Edison has brought his telephonic experiments to so successful an issue that his carbon transmitter and his new receiver leave little to be desired in electric telephony, except the automatic record of the received speech, and this, it is not impossible, may ere long be accomplished.

The object Mr. Edison sought to attain was a variation in the resistance of the circuit proportional to the motions of the vibrating diaphragm of the transmitter. Gray employed for this purpose a liquid resistance, but owing to the fact that all suitable liquids are decomposed by the current, Edison abandoned them and tried solid conductors. He remarks in Prescott's work on the telephone:—

"In the spring of 1876, and during the ensuing summer, I endeavoured to utilise the great resistance of thin films of plumbago and white Arkansas oil-stone, on ground glass, and it was here that I first succeeded in conveying over wires many articulated sentences."

A spring attached to the vibrating diaphragm was arranged so as to cut in and out of the circuit more or less of the plumbago film. But the results were not very favourable. In January, 1877, a new device occurred to Edison, namely, the employment of a peculiar property which semi-conductors have, of varying their resistance under pressure.[1] For this purpose

[1] Continued from p. 14.

[2] We have already considered in a previous article the historical facts connected with this discovery, and therefore it will be needless to refer to this point here. A reference to the *Journal Télégraphique* of Berne for 1874, wherein it was asserted M. Clérac had anticipated the use Mr. Edison has made of the varying resistance of carbon dust under varying pressures, fully confirms the statement we made in our last article that the merit of this application is not due to M. Clérac at all, who simply used *permanently compressed carbon dust* as a rheostat.

the diaphragm was made to press against a little cylinder of crude plumbago. The articulation was poor, though conversation could be understood. Investigation showed that the difference of resistance produced by varying pressure was exceedingly small. As so small a change in a circuit of large resistance was but a small factor, whereas a slight change of resistance in the primary circuit of an induction-coil would be an important factor, it occurred to Edison to associate an induction-coil with his arrangement. But difficulties arose from the high resistance of the plumbago cylinder he first used. Ultimately he constructed a transmitter in which a thin slice or button of a semi-conducting substance was placed between two platinum discs. Electrical connection between the button and discs was maintained by the slight pressure of a piece of rubber tubing which was secured to the diaphragm, and also made to rest against the outside disc. The vibrations of the diaphragm were thus able to produce the requisite variations of pressure on the button and thereby create corresponding variations in the resistance in the primary circuit of the induction coil; which in turn gave rise to a corresponding series of induced currents in the secondary. Finally, these induced currents were transmitted through the line and received at the far end by an ordinary magneto-telephone. Fig. 1, for which we are indebted to the *Telegraphic Journal*, shows the arrangement.

At first a button of solid plumbago, such as is employed by electrotypers, was used, and the results obtained were considered excellent, everything transmitted coming out moderately distinct, but the volume of sound was no greater than in that of the magneto-telephone. Numerous other semi-conductors were tried until Edison hit upon some lamp-black that had been taken from a smoking petroleum lamp and preserved as a curiosity on account of its intense black colour. A small disc was made of this substance, and when placed in the telephone it gave splendid results, the articulation being distinct, and the volume of sound several times greater than with a pair of telephones worked on the magneto principle. It was soon found upon investigation that the resistance of a disc formed of this substance could be varied from 300 ohms to the fractional part of a single ohm by pressure alone,[1] and that the best results were obtained when the resistance of the primary coil, in which the carbon disc was included, was six-tenths of an ohm, and the normal resistance of the disc itself three ohms.

The rubber tube between the diaphragm and the disc gave some trouble on account of its tendency to become flattened. Experiments undertaken with a view to remedy this defect led Edison to discover that not only could a rigid substance be interposed with advantage, but that the vibrating diaphragm even was unnecessary; that, in fact, the sound-waves could be transformed into electrical pulsations without the movement of any intervening mechanism. Edison states that the manner in which he arrived at this result was as follows:—

"I first substituted a spiral spring of about a quarter-inch in length, containing four turns of wire, for the rubber tube which connected the diaphragm with the discs. I found, however, that this spring gave out a musical tone which interfered somewhat with the effects produced by the voice; but, in the hope of overcoming this defect, I kept on substituting spiral springs of thicker wire, and as I did so I found that the articulation became both clearer and louder. At last I substituted a solid substance for the springs that had gradually been made more and more inelastic, and then I obtained very marked improvements in the results. It then occurred to me that the whole question was one of pressure only, and that it was not necessary that the diaphragm should

[1] The present writer can confirm this statement, but everything depends on the exact quality of the lampblack, the least trace of overheating lessens its intense blackness and enormously diminishes its conductivity.

vibrate at all. I consequently put in a heavy diaphragm, one-and-three-quarter inch in diameter and one-sixteenth inch thick, and fastened the carbon disc and plate tightly together, so that the latter showed no vibration with the loudest tones. Upon testing it I found my surmises verified: the articulation was perfect, and the volume of sound so great that conversation carried on in a whisper three feet from the telephone was clearly heard and understood at the other end of the line."

The present and modified form of the instrument is shown in the next diagram, where A A is the thick iron diaphragm, B the rigid connecting-piece pressing together the metal discs D D and the carbon disc C. The pressure can be regulated by the screw S acting upon the sliding stem E, which terminates in an insulating cup that encloses the carbon and metal discs. Wires lead from D D to binding screws.

It has been urged that Edison was led to adopt this arrangement by the discovery of the microphone, it is therefore of historical interest to note that in the *American Journal of the Telegraph* for April 16, 1878, it is stated "In the latest form of transmitter which Mr. Edison has introduced, the vibrating diaphragm is done away with altogether." A week or two later the discovery of the microphone was announced, and the transmission of speech without a vibrating diaphragm aroused universal surprise; the loose contacts which are essential to the microphone are, however, fatal for telephonic purposes.

It must be understood that the carbon telephone only acts as a transmitter; it is incapable of reconverting the electric pulsations into sonorous vibrations. For this purpose the ordinary magneto-telephone is employed.[1] The accessories and electrical connections requisite for use in a carbon telephone circuit are shown in the next diagram (Fig. 3).

P P is the primary wire of an induction coil having a resistance of several ohms and placed outside instead of, as is usual, inside the secondary coil *s*, which has a resistance of some 200 ohms.[2] R is the receiving magneto-telephone and T the transmitting carbon telephone; either one or the other can be thrown into the circuit by means of the switch K. When a plug is inserted at the bottom of the switch between 3 and 4, the relay or sounder S, battery B, and key in the centre of the figure, are included in the main line circuit. This is the normal arrangement of the apparatus for signalling purposes. To call the distant end the key is pressed down two or three times; by this means battery currents are sent through the primary coil P, the currents thus induced in the secondary coil *s*, pass to line, and actuate the relay or sounder in the distant instrument. When a plug is inserted at the top, between 1, 2, and 4, the apparatus is available for telephonic communication. By tracing out the connections it will be seen that in this latter case the battery, B, the primary wire of the coil, P, and the transmitter, T, are in short circuit, and at the same time the line wire is in circuit with the secondary coil, *s*. A general view of the arrangement is shown in Fig. 3, for which we are indebted to the publishers of Count du Moncel's book on the telephone. The lettering is different, but the respective parts can be readily understood. In this case a polarised relay and electric call-bell are employed instead of the sounder, a necessary addition in long circuits.

Concerning the actual performance of the carbon tele-

[1] The use of the Bell telephone as a receiver in Edison's instrument is at present the subject of legal proceedings; Edison, however, claims to have used the magneto-receiver before Bell invented it, and we learn that a letter has recently arrived from Mr. Edison stating that he has now constructed a still better and novel receiver for his telephone. Edison remarks: "Batchelor, one of my assistants, heard a whisper last night fifteen feet away from the receiver, and ordinary conversation comes out as loud as originally spoken." Further information about this receiver is given at the close of this article.

[2] In the last improvements the usual position of the primary and secondary coils has been reverted to; the resistance of the former for short circuits should be about a third of an ohm and of the latter somewhat over seventy ohms.

phone, it is stated in Prescott's work on the telephone that Mr. Bentley, President of the local telegraph company at Philadelphia, has succeeded in working with it over a wire of 720 miles in length, and has found it a

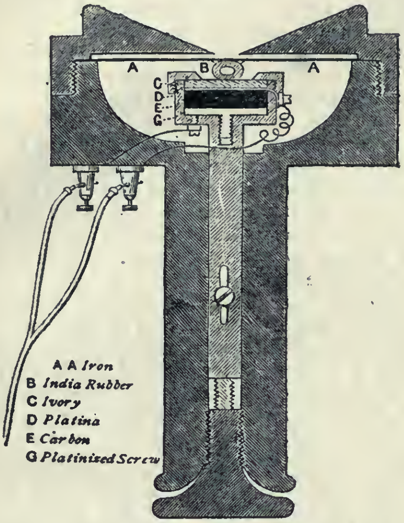

FIG. 1.—Section of Carbon Telephone—Early form.

practicable instrument upon wires of 100 to 200 miles in length, notwithstanding the fact that the latter were placed upon poles with numerous other wires, which occasioned sufficiently powerful induced currents in them

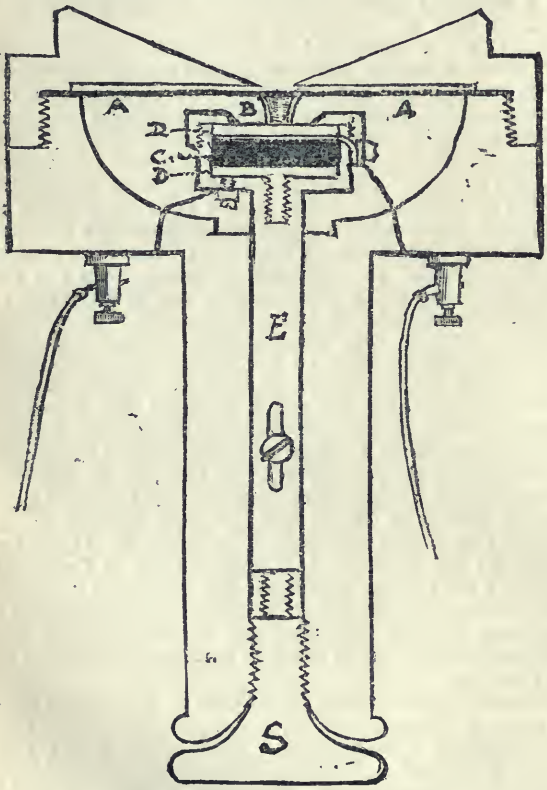

FIG. 2.—Section of Carbon Telephone—Latest form.

to entirely destroy the articulation of the magneto-telephone. Further, he has found the instrument practicable "*when included in a Morse circuit,* with a battery and eight or ten stations, provided with the ordinary Morse apparatus; and that several way stations could exchange business telephonically upon a wire which was being worked, quadruplex, without disturbing the latter, and notwithstanding, also, the action of the powerful reversed currents of the quadruplex on the diaphragms of the receiver. It would thus seem as though the volume of sound produced by the voice with this apparatus more than compensated for the noise caused by such actions." Mr. Edison's assistant, Mr. Adams, now in England, states that conversation has been carried on during the night between New York and Chicago, places nearly 1,000 miles apart; and that under less favourable circumstances during the day the carbon telephone has been successfully used over a line of about half this length. Mr. Adams also informs the writer that at the Paris Exhibition he was able to transmit the music of a piano from Paris to Versailles, a distance of more than 20 miles; the piano standing 50 feet from the carbon telephone and yet not a note was lost at Versailles.

The present writer has had an opportunity of testing

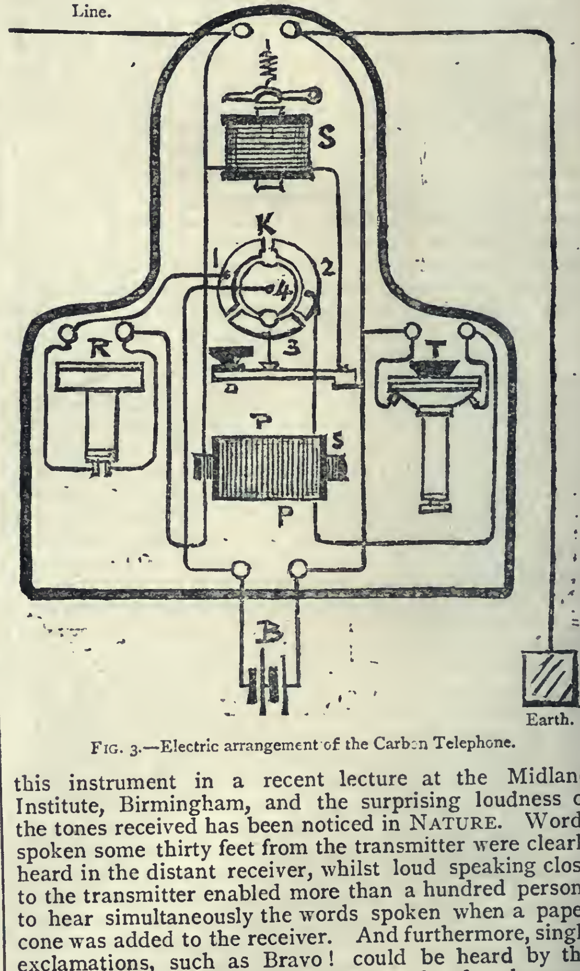

FIG. 3.—Electric arrangement of the Carbon Telephone.

this instrument in a recent lecture at the Midland Institute, Birmingham, and the surprising loudness of the tones received has been noticed in NATURE. Words spoken some thirty feet from the transmitter were clearly heard in the distant receiver, whilst loud speaking close to the transmitter enabled more than a hundred persons to hear simultaneously the words spoken when a paper cone was added to the receiver. And furthermore, single exclamations, such as Bravo! could be heard by the whole of a crowded audience of upwards of a thousand people. Even when the line wire was broken, the fractured ends being near to, but not touching each other, conversation could still be carried on through the circuit with the carbon telephone, though communication by the magneto-telephone and the ordinary telegraphic instruments was entirely interrupted. The writer has also just made further and more severe trials with this instrument on, he believes, the longest private wire in constant use in England, namely, that belonging to Messrs. Colman,

of Norwich and London, which firm have before this kindly allowed their wire to be freely used for experimental purposes. This wire stretches from Messrs. Colman's works at Norwich to their office in Cannon Street, a distance of a little over 115 miles. The wire runs on the same poles as the numerous other wires of the Great Eastern Railway, and is carried overhead from the terminus in London to Cannon Street. At 4 o'clock the experiments began, and the incessant crackling and bubbling sounds in the receivers revealed the fact that the adjoining telegraph wires were at their busiest, and that induction could hardly be worse. Nevertheless, the first exclamation uttered into the hastily adjusted carbon telephone at Norwich was heard perfectly in the

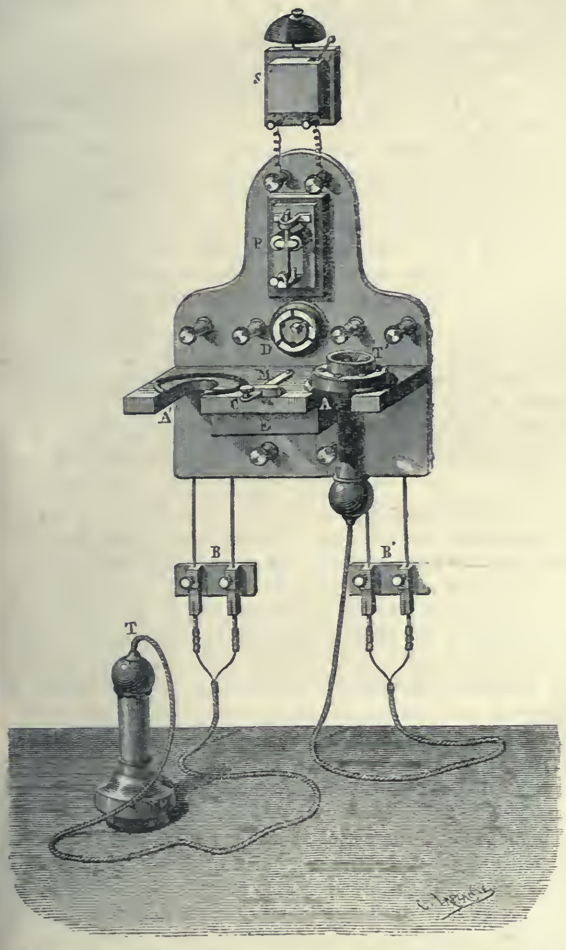

FIG. 4.—General view of the arrangements and accessories of the Carbon Telephone.

counting-house at Cannon Street. Conversation then ensued between the two places; some words were occasionally lost, but the American accent of Mr. Adams, Mr. Edison's professional assistant, who had charge at the Norwich end, was distinctly recognisable in London. Remarks passed on the weather showed that a storm of snow and sleet was going on at both ends, and the insulation therefore almost at its worst. Later on, towards 9 o'clock in the evening, the effects of induction grew less, but were still considerable. The voices from Norwich were now louder, the individuality of the speakers more marked, and conversation could be carried on without difficulty, the voices of certain speakers being remarkably distinct.

Twelve months previously the writer had an opportunity of trying Bell's telephone on the same circuit, when not a word could be transmitted during the day, owing to induction, but at night everything was clearly heard; hence the foregoing experiments established the important fact that in spite of powerful induction operating against it, the Edison telephone is a practicable instrument. It is true that before this telephone can be commercially used, especially during the day and on long lines, special electrical adjustments of the instruments must be made such as the pressure on the carbon and probably the resistance of the induction coil relatively to the line, but in this there is no inherent difficulty, and the adjustment once made no further change is likely to be necessary. Meanwhile we shall await with curiosity the new receiver, which, in a recent letter to the writer, Edison says will arrive in England soon; they differ from other telephones in having "no ear pieces or magnets about them," and according to Edison, "are about twenty times louder than any magnetic telephone, and can, if desired, reproduce the voice at the distant end louder than originally spoken, whilst the whole affair is even cheaper and simpler than the receivers now in use."

It is not impossible that before very long, by means of the Edison telephone, speeches in Parliament may be telephonically transmitted to the newspaper offices and to the country, whilst honourable members, if their articulation be distinct, are speaking from their ordinary places in the House. W. F. BARRETT

NOTES

THE Corporation of Penzance are, we hear, making preparations to celebrate the centenary of Sir Humphry Davy's birth next month. The Paris Academy of Sciences, who awarded Davy a prize in 1807, when war was raging between France and England, will probably take some part in the celebration.

A COMMITTEE has been formed at Heilbronn with the object of erecting a monument to the memory of Dr. Robert Julius Mayer in his native place. Every one knows that Dr. Mayer's name is associated with the establishment of the mechanical equivalent of heat (see NATURE, vol. xvii. p. 450).

THE Observatory of Geneva has received the gift of an instrument of large dimensions by the generous munificence of its director. Prof. Emil Plantamour, who has occupied this position for about forty years, has constructed, at his own expense, in the existing building, a turret of 7 metres in diameter, surmounted by a cylindrical cupola, in which will be placed an equatorial telescope of 10 French inches aperture and 3·70m. focal distance. The object-glass has been ordered from Merz, of Munich, and the equatorial mounting is being manufactured at the workshop of the Geneva Society for the Construction of Physical Instruments. It is hoped that the new instrument will be in working order about the end of next spring.

DR. CREIGHTON, Demonstrator of Anatomy at Cambridge, has joined the editorial council of the *Journal of Anatomy and Physiology*, which henceforth adds to its title the words "normal and pathological."

WE would call the attention of our readers to a paper, likely to be of some interest, to be read at the meeting of the Physical Society on Saturday, by Messrs. Ayrton and Perry. The title of the paper is "The Music of Colour and of Visible Motion," and from what we can learn of Messrs. Ayrton and Perry's investigations, they claim to have hit on a new emotional art. By means of a new machine which they have devised they can produce combinations of harmonic motions with greater variety than can be obtained with any existing machine. Their idea, we believe, is that, judging from their experience partly of the feelings produced by large bodies in rapid motion and partly from the fact that in Japan posturing takes the place of the operatic

singing of the West they think that colour and motion may be made to produce emotions like good music, and therefore may very likely be employed as adjuncts in the entertainments of the future intended to work on the emotions.

AT a meeting of the Medical Society at University College, Gower Street, on December 3, at 8 P.M., an address on "The Use of Physiology to Medical Students," will be delivered by Dr. Michael Foster, F.R.S.

AT the monthly meeting of the Linnean Society of New South Wales, on September 30, the committee appointed to consider Baron Miklucho-Maclay's suggestion for the establishment of a zoological station at Sydney, presented their report affirming the desirability of forming such an institution. The Hon. W. Macleay having very liberally offered to afford facilities for a temporary zoological station in the vicinity of his residence, and promising the use of his museum, library, and microscopes to students of natural history, the Society adopted the report, and it was agreed to commence operations at once.

FROM a promising new American fortnightly journal, *Science News*, edited by Messrs. W. C. Wyckoff and E. Ingersoll, we learn that Prof. S. P. Langley, director of the Alleghany Observatory, has just started on a voyage to Europe, being commissioned by the United States Coast Survey to make observations to serve as a standard of comparison in determining the requisites for astronomical stations in American territory. The inquiry will have particular reference to the effects of different elevations and atmospheric conditions upon the fitness of various localities for the practical work of astronomy. Prof. Langley goes direct to Paris and thence to Italy; the trip will include an ascent of Mount Etna. In addition to the routine work of the Alleghany Observatory, Prof. Langley has been busily engaged in completing a direct experimental comparison between the heat of the sun and the highest heats attainable in the arts. The results indicate that the sun's *intrinsic* heat is almost beyond comparison greater than that of any blast furnace, and far larger than was reckoned by the French physicists. Prof. Langley has also nearly finished a memoir embodying great numbers of measurements and drawings at the extreme lower end of the solar spectrum, particularly the A group. These are parts of a research supported by the Rumford fund, requiring also a new study of the distribution of energy in the spectrum, as shown by the thermopile: Prof. Edison's tasimeter will probably be tested in the course of the work, using the Rutherfurd gratings to supply the spectra. A great improvement, Prof. Langley hopes, has recently been made by him in the accessories of the diffraction spectroscope, by means of which the use of collimators of extraordinary length will become practicable.

MR. C. E. ALLAN writes that he has constructed a rough pencil microphone, using cinders instead of carbon. This construction was not sensible to small sounds, but speech was transmitted very clearly. The pressure at the points of contact was increased by winding wire round the cinder pencil, and by this means the jarring sound of the cinders was almost totally removed, so that songs, the notes of an organ, and the ordinary tones of the voice were distinctly transmitted.

THE annual exhibition of the Haggerston Entomological Society takes place at 10, Brownlow Street, Dalston, to-day and to-morrow, at six P.M. This exhibition is always well worth a visit.

A CORRESPONDENT in the *Times* states that Mr. Edison, in reply to a telegram, avers that, according to his system, the altering of one light does not in the slightest degree affect others in the same circuit. He can adjust the brilliancy of each light at pleasure, it is stated, so that thus electrical lighting would be as steady and as much under control as gas itself. "Whatever method he uses, Mr. Edison appears confident of the success of his system." Mr. Sawyer, being interviewed by a New York reporter on the subject of his lamp, said he did not claim the incandescence of carbon in a sealed receiver as an idea of his own, but had utilised it in the development of other ideas. He claimed a form of conductor which would radiate the heat produced by the incandescence in such a way that the globe would be heated only at the point where the light was. He had also patented a process for charging the receiver with pure nitrogen gas and entirely displacing the atmospheric air. He had patented a means of so closing the receiver that no atmospheric air could find its way into the interior. The nitrogen, he claimed, would last for ever. Besides, there was a substance in the bag at the bottom of the lamp which would absorb oxygen and carbonic acid gas. These, he said, were his improvements. One lamp had been in use two or three hours daily for three months, until a sudden jarring of a door broke it. There had never been any flaking or change in the carbons used. The only change the carbon underwent was its purification. Before being lit it was a dead black; after being incandescent for a time it took on the silver gray colour characteristic of pure carbon. The sub-division of the light, as produced by Mr. Sawyer's system, consists of branch wires leading from the two main wires of the engine. Each of these branches is calculated to supply a number of lamps. The extension of the main wires necessitates an increased heaviness of the wire for each mile. In lighting New York a radius of only half a mile from each supply station will be actually necessary.

THE Liverpool Corporation are taking steps to utilise the electric light as a public illuminating medium as soon as it is utilisable. They intend to apply to Parliament next session for powers to this purpose, have appointed a committee to watch over the subject, and have despatched their engineer to the Continent to examine into the use of the light in Paris and elsewhere.

A *Daily News* correspondent writing from Naples on the 13th inst. states that the stream of lava from Vesuvius was slowly extending from the cone towards the Atrio del Cavallo, the ravine or valley which separates Vesuvius from Somma. The stream extended almost the whole way into the Atrio del Cavallo, and divided into no less than three large streams. These were increasing in size and extent, and the slight shower of lava had also increased, but it was not sufficient to be observable from Naples.

AN earthquake took place at Sierra Leone on the morning of October 11, shaking every house in the colony, and causing great alarm to the inhabitants, but fortunately no damage of any moment was done. There were three successive shocks felt, travelling inland to a distance of about sixty miles, and the end of each is said by some to have resembled three very heavy peals of thunder following quickly upon each other. The natives in the interior were so terrified that in many cases they deserted their villages. An earthquake of a similar character occurred about fifteen years ago.

A M. BAILEY, of Paris, has invented an electric spark pen which possesses some points of interest. If a sheet of thin paper is attached to a plate of copper or zinc, it is stated that an engraving may be made with extraordinary facility by means of this pen. If one of the poles of a Ruhmkorff machine is attached to the plate and the other to the upper end of the pen, the current will run through, and in drawing the paper is perforated. When the drawing is finished, ink is laid on with an ordinary roller, and the greasy fluid penetrates through the holes. The plate is then plunged in water, which detaches the paper, and it is ready for immersion in the acid. The advantage claimed for this method is that the artist does all parts of his work and has no more trouble than if he were working with an ordinary pencil. He can even work in a dark room without any other light than the glare from the induction spark.

THE *Times* Geneva correspondent states that the remains of another lake village have just been brought to light at Lorcas by the shrinkage of the waters of the Lake of Bienne. This appears to be one of the most interesting discoveries of the sort we have had for some time, rich as have been the last few weeks in notable lacustrine finds. The station at Lorcas, assigned by experts to the age of stone, is situated at a short distance from the lake shore, not far from another and similar station which was explored in 1873. An exploration, conducted by Dr. Gross, of Neuveville, has resulted in the gathering of many novel and interesting objects, pierced stone hatchets similar to those found in Denmark, large flint lance-heads, jade hatchets with stag-horn and wooden hafts fastened with pitch; vessels in wood, among others a colander, and a vase in a good state of preservation. Near these were found several arms and instruments of pure copper, a circumstance which points to the probability that intermediate between the age of bronze and the age of stone was a period when prehistoric man had not discovered the art of alloying copper with tin. This was the age of copper. Still more remarkable is a find of human skulls which bear unmistakable marks of having been trepanned. Round pieces have been cut out, doubtless after death, as is supposed, for use as amulets. In some instances pieces were cut from the craniums of living infants in order, as M. Broca conjectures, to let out the spirit by whose malignant influence they were afflicted with fits, convulsions, and other maladies. These bits of infants' skulls were sometimes used in a way of which an example has been found at Lorcas; they were put inside the heads of the dead to protect them from the wiles and assaults of evil beings in the world of spirits.

A PORTRAIT of the Rev. M. J. Berkeley has been presented to the Linnean Society; it was painted by Mr. Peale at the instance of some of Mr. Berkeley's friends.

M. ROUX has sent to the Society of Encouragement of Paris the results of his experiments on nitro-glycerine, from which it appears that bottles of tinned iron falling from a great height and breaking do not cause a dangerous explosion.

WE have received an interesting syllabus of a course of ten lectures on literary and scientific subjects, to be delivered in the lecture theatre of the Bristol Museum, during the winter.

MR. BROTHERS, photographer, Manchester, asks us to state that the portrait of Sir George Airy, which we gave in a recent number, was from a photograph by him. The copy from which our portrait was taken did not indicate by whom it was photographed.

THE *Yama Sentinel* of California gives an account of a singular specimen of meteoric iron, which resembled steel, that had been found in the Mohave desert. It weighs about a pound, has some free gold on the surface, is not magnetic, and has successfully resisted the action of various acid baths. One of its surfaces shows a fracture of crystalline appearance, the colour of which is steel gray tinged with yellow. It has defied the best cold chisels, and has neither broken nor chipped under heavy blows. If its composition could be imitated it would be the hardest and toughest alloy known.

BEING at Osaka recently, a correspondent of the *Kobe Advertiser* was invited to inspect the cotton-mills and spinning-factory which was established at Sakai some years ago, but has attracted little notice. The account which he gives of his visit furnishes additional testimony of the progress which the Japanese are so rapidly making. The premises in question cover 7,000 tszuboes of ground, and the buildings thereon are substantially and well built, and the greater part of the machinery was imported from England. It is not necessary to enter upon the description of the internal arrangements of the establishment, but it is interesting to learn that "in this factory are employed about 150 hands, some 60 men and boys, a few elderly females, and about 80 girls. These latter resemble much the factory girls at home; the same merry countenances and laughing twinkling eyes, unabashed, but perfectly orderly, though perhaps a little negligent upon the appearance of visitors. . . . . We were highly gratified with our visit, showing as it did that there is a wide and very hopeful field for the development of industries in Japan."

WE have on our table the following books :—"Mathematical Drawing Instruments," by W. Ford Stanley, E. and F. N. Spon; "Crystallography," Henry Palin Gurney, S.P.C.K.; "Outlines of the Geology of Northumberland," G. A. Lebour, H. Sotheran and Co.; "Coal and Iron in all Countries of the World," John Pechar, Simpkin and Co.; "Abriss der praktischen Astronomie," Dr. A. Sawitsch, Wilhelm Manke; "A First Catechism of Botany," John Gibbs, Durrant; "The Present State of Electric Lighting," J. N. Schoolbred, Hardwick and Bogue; "The House-Surgeon," Alf. Smee, F.R.S., Accident Insurance Company; "The Geological Record for 1876," edited by William Whitaker, Taylor and Francis; "Etna," G. F. Rodwell, Kegan Paul and Co.; "Spiritual Science," Kuklos, John Harris; "Instructions for Testing Telegraph Lines," Vol. I., Louis Schwendler, Trübner; Health Primers—"Premature Death—Alcohol," "Exercise and Training," "The House," Hardwick and Bogue; "Gegenbaur's Elements of Comparative Anatomy," translated by F. Jeffrey Bell and E. Ray Lankester, Macmillan and Co.

MR. E. P. RAMSAY, Curator to the Australian Museum, Sydney, has prepared and issued "Hints for the Preservation of Specimens of Natural History for Museum Purposes." This short pamphlet contains useful directions for unskilled taxidermists, and notes on the preservation of entire animals of small size. It contains occasional remarks on Australian animals, and suggestions specially appropriate to the wants of naturalists in the bush; these are the only novelties. It will be seen that the title is rather too comprehensive for the contents of the paper; and now that we are beginning to look a little beyond the mere collection of dried skins, it is disappointing to find the internal organs of animals treated as so much matter to be got rid of.

THE last volume of *Medical Reports*, issued by order of the Inspector-General of Customs in China, contains a contribution of considerable interest to our knowledge of the geographical distribution of disease. The notes we refer to, which are by Mr. E. Rocher, of the Customs' Service, prove that the plague exists in China, and that it has in late years spread over a larger area than is generally known. They also show that the disease did not, as some believe, entirely disappear between 1844 and 1873, and it is thought by no means improbable that it may have passed from Yünnan to Mesopotamia or Persia. In Yünnan the disease is known as *Yang-toze*, and is believed to have been originally imported from Burmah. When that was it is impossible to determine, but since the commencement of the civil war it has spread over the whole province, decimating the population. There is one fact which inclines Mr. Rocher to think that the epidemic is owing to exhalations from the soil, viz., that those animals which live in the ground, in drains, or in holes, are the first to be attacked, and this is particularly noticeable with rats. As soon as these animals are ill they leave their holes in troops, and, after staggering about and falling over each other, drop down dead. The same phenomenon occurs in the case of other animals, such as buffaloes, oxen, sheep, deer, pigs, and dogs; all are attacked, but the dog less severely than the others. When these phenomena appear it is not long before the disease spreads to man, and, knowing this, the people do

what they can to guard themselves against it. They begin to purify their houses by lighting fires in every room, and in certain towns they abstain from pork. Mr. Rocher gives details as to the symptoms and course of the disease. With regard to the track of the epidemic Mr. Rocher observed a peculiar fact both in the north and south of the province. Instead of visiting every village in its direct line of progress it would pass some completely by, visiting places near them and on both sides, to return to those forgotten spots several months afterwards, when the epidemic would appear to have passed far away. Another fact not less curious is that after having appeared in almost every one of the villages scattered about the plains, it frequently ascends the mountains, where, among the aborigines who inhabit the high lands, it claims many victims. We may add that Mr. Rocher's notes are accompanied by a map, compiled from private and official memoranda, which shows the course followed by the plague in 1871, 72, and 73; it was not possible, however, to include in it the towns in the west of the province, which was at that time the theatre of the war between the Imperialists and the Mahometan rebels, as the information obtainable was quite untrustworthy, but it is certain that the epidemic was constantly present among the Imperialist troops.

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Miss G. E. Marryat; a Bonnet Monkey (*Macacus radiatus*) from India, presented by Mr. F. Hinde; two Horsfield's Tortoises (*Testudo horsfieldi*) from Turkestan, presented by Dr. Alex. Strauch, C.M.Z.S.; a Wanderoo Monkey (*Macacus silenus*) from Malabar, two Egyptian Jerboas (*Dipus ægyptius*) from Egypt, a Sun Bittern (*Eurypyga helias*) from South America, deposited; a Woodcock (*Scolopax rusticola*), European, purchased.

CHARLES ADOLPHE WURTZ

IN connection with the Faraday Lecture which follows, it may interest our readers to have a few particulars as to the life and work of the lecturer, Prof. Wurtz.

Charles Adolphe Wurtz was born at Strassburg on November 16, 1817. He commenced his chemical career as assistant to Dumas, and first acquired an independent position as professor at the Agricultural Institute at Versailles. For the last thirty years he has been Professor of Chemistry at the École de Médecine, Paris; in addition to which he now holds the post of Professor of Chemistry at the Sorbonne.

Prof. Wurtz is a member of the Institute (Académie des Sciences), and a foreign Fellow of the Royal Society.

Some idea of the energy which he has displayed as an investigator is conveyed by the fact that a list of no less than seventy-three titles of papers is appended to his name in the Royal Society Catalogue, which only includes papers published previous to 1864. Much of his work is of the first importance in connection with chemical theory, and he undoubtedly takes rank as one of the chief pioneers of modern organic chemistry.

His first investigation, published in 1842, was on the constitution of the hypophosphites; this was followed by researches on phosphorous acid, sulpho-phosphoric acid, &c., which greatly added to our knowledge of the phosphorus compounds. It was in the course of his experiments on the hypophosphites that Wurtz discovered hydride of copper, Cu_2H_2, one of the most remarkable hydrides with which we are acquainted, and especially interesting as, with the exception of potassium, sodium, and perhaps palladium, none of the metals appear to be capable of combining with hydrogen. Hydride of copper is formed as a yellowish precipitate on adding a concentrated solution of copper sulphate to a solution of hypophosphorous acid, and warming the mixture to about 70° C.; in the dry state it slowly decomposes into its constituents at about 55° C.; concentrated hydrochloric acid at once dissolves it with evolution of hydrogen, although copper is not in the least affected by this acid, and what is most remarkable, both the hydrogen of the acid and of the hydride of copper are given off as shown by the equation—

$$Cu_2H_2 + 2HCl = Cu_2Cl_2 + 2H_2.$$

The study of certain cyanogen compounds—the cyanic and cyanuric ethers—next engaged his attention, and his researches on these bodies culminated in the remarkable discovery, in 1849, of the so-called compound ammonias formed by the displacement of one of the atoms of hydrogen in ammonia, NH_3, by organic radicles, such as methyl, CH_3, ethyl, C_2H_5, &c.

A third investigation to which we may here refer is that on the alcohol radicles published in 1855. Frankland had shown that the hydrocarbon radicles which it was assumed were contained in the alcohols could actually be isolated; that, from ordinary or ethyl acohol, for example, which may be regarded as a compound of the radicle ethyl, C_2H_5, with the radicle OH, we may obtain ethyl by acting with zinc on the iodide which it yields on treatment with hydriodic acid, thus withdrawing the iodine from it, just as the iodine is withdrawn from the hydrogen in hydriodic acid by the action of metals; and Kolbe had obtained similar results with acids, such as acetic acid, by submitting solutions of their salts to the action of a powerful electric current. These chemists, however, supposed that the radicles thus withdrawn from combination with other radicles remained in the free state, but Laurent and Gerhardt, and Hofmann argued on theoretical grounds that the bodies thus produced were not the radicles themselves but compounds of the radicles with themselves—that ethyl, for example, was not C_2H_5, but C_4H_{10} or $C_2H_5 + C_2H_5$. Conclusive evidence of the correctness of this latter view was afforded by Wurtz's discovery that if a mixture of the iodides of two different radicles were treated with metallic sodium, a hydrocarbon formed by the union of the two different radicles was obtained. This discovery has afforded one of the chief arguments in favour of the view now almost universally entertained by chemists, that free hydrogen is a compound of hydrogen with hydrogen.

The mere recapitulation of the titles of his remaining investigations would alone occupy a large amount of space. We can only refer to those on the glycols and on ethylene oxide; on the action of nascent hydrogen on aldehyde; on the action of chlorine on aldehyde, both in the anhydrous state and in presence of water; on the action of hydrochloric acid on aldehyde; on the synthesis of neurine; and on abnormal vapour densities, as being, among others, of especial interest.

ON THE CONSTITUTION OF MATTER IN THE GASEOUS STATE[1]

LADIES AND GENTLEMEN,—

I ESTEEM it a great honour to address you within these walls, about which there still hovers the ever fresh memory of him whose name we celebrate to-day, while we deplore his loss. I am fully sensible both of the great value of this honour and of the danger that attends it, and I have need to shelter myself under the authority of the great name of FARADAY. I have, therefore, chosen a subject connected with his earliest discoveries. The constitution of matter is a question of the highest importance with regard both to physics and to chemistry.

The word "gas" was introduced into science by Van Helmont, who, at the beginning of the seventeenth century, first pointed out, with some degree of precision, the differences existing be-

[1] The Faraday lecture, delivered before the Fellows of the Chemical Society, in the Theatre of the Royal Institution, on Tuesday, November 12, 1878, by Ad. Wurtz, Membre de l'Institut; Doyen Honoraire de la Faculté de Médecine de Paris.

tween certain aëriform fluids. He it was who first spoke of *Gas silvestre*, formed by the combustion of charcoal, and given off during the fermentation of beer. To him, also, we owe the distinction—which kept its ground for two centuries—between gases and vapours. He regarded gases as aëriform fluids, incapable of reduction to the liquid state by cooling, whereas vapours require the aid of heat to maintain them in the gaseous state. An important difference of constitution seemed, therefore, to exist between these two kinds of aëriform fluid. This difference, however, is not fundamental, and the distinction between gases and vapours has disappeared, in a theoretical point of view, being, in fact, reduced to a simple question of temperature and pressure.

On March 13, 1823, Faraday, then a young man engaged as chemical assistant at the Royal Institution, read before the Royal Society a note entitled "On Fluid Chlorine." He had succeeded in condensing this gas to a liquid by a process which has become classical. This process consists in heating in a closed vessel placed in a water-bath crystals of chlorine hydrate. This compound, very rich in chlorine, is resolved at a gentle heat into chlorine and liquid water, the quantity of which is not sufficient to dissolve the whole of the chlorine. The latter is therefore disengaged in great part in the state of gas, which accumulates in the small space remaining to it, and is liquefied by the pressure which it exerts upon itself.

On the same day Sir Humphry Davy read a note "On the Liquefaction of Hydrochloric Acid Gas," which he effected by decomposing sal-ammoniac with sulphuric acid in a closed vessel. These researches were completed by Faraday, who, on April 10 of the same year, described the liquefaction of a large number of gases, directing his efforts, by Davy's advice, chiefly to those which are dense, or very soluble in water, such as sulphurous acid, ammonia, sulphuretted hydrogen, carbonic acid, and protoxide of nitrogen.

To enumerate the special processes adopted in each particular case would occupy too much time. We shall therefore merely observe that the chief, if not the only, means of condensation adopted in these experiments was compression, that is to say, the reduction of the gas to a small volume, and that this compression was exerted by the gas upon itself, as it accumulated in the very strong sealed glass tubes in which it was disengaged. Sir Humphry Davy, in the note above cited, had remarked that pressure appeared to be a more efficacious method of condensation than cooling, inasmuch as a double pressure reduces the volume of the gas to one-half, whereas a depression of temperature of 1° F. reduces the volume by only $\frac{1}{480}$, the lowering of temperature, moreover, soon attaining an impassable limit. It must, however, be especially observed that, even in his first experiments, Faraday made use of differences of temperature, if not to liquefy the gases, at all events to distil and isolate the liquids. Thus it was in the case of chlorine, for example, and in that of ammonia, which he liquefied by heating ammoniacal silver chloride in a bent tube sealed at both ends, the liquid ammonia then distilling over and collecting in the empty branch of the tube, which was cooled to a low temperature.

Similar phenomena will be exhibited in the experiment which I am about to show you, consisting in the liquefaction of cyanogen gas by heating cyanide of mercury in a small glass tube terminated by a long capillary tube bent in the form of the letter U. The figure of this curved portion will be projected on a screen by the electric light, and in a few seconds you will see the liquid cyanogen collect in the bend.

Before leaving this part of my subject, I would recall to your attention two of Faraday's discoveries resulting from the application of the principles just explained. Having compressed coal-gas to twenty-five atmospheres, Faraday in 1825 discovered two important bodies, namely, butylene, a compound of great importance in a theoretical point of view—and benzene—so named by Mitscherlich several years afterwards—which in our own time has become the object of numerous and important applications, and the pivot of an entire department of chemistry.

Another instance is afforded by sulphurous acid gas (SO_2), which was liquefied by Bussy in 1824, at the ordinary atmospheric pressure, by the effect of a cold of 12° to 15° below zero.

Whether we condense gases by pressure or reduce them to the liquid state by diminution of temperature, the result of either method is to bring their particles closer together. It would seem then, in accordance with Davy's view, that pressure ought to be more efficacious, as a means of condensation, than cooling. Nevertheless it is not so. The mere approximation of the particles of certain gases does not suffice to effect their liquefaction, and moreover, the distances between the particles cannot be diminished indefinitely by pressure alone. M. Natterer, of Vienna, has compressed oxygen, hydrogen, and nitrogen to 3,000 atmospheres without effecting their liquefaction. These gases, hitherto called permanent, cannot be liquefied by pressure alone, and their liquefaction, which has quite recently been effected, is the joint effect of strong pressure and a great degree of cold. This is the important point, and I request your permission to offer in this place a few explanations which will serve to place it in its true light.

The impossibility of liquefying certain gases by pressure alone is in accordance with the ideas which are current at the present day respecting the nature of aëriform fluids, and likewise with a discovery made in England within the last few years, on the continuity of the gaseous and liquid states. I will explain myself briefly on these two points.

Daniel Bernouilli first enunciated the idea that gases are formed of material particles, free in space, and animated by very rapid rectilinear movements, and that the tension of elastic fluids results from the shock of their particles against the sides of the containing vessels. Such is the origin of the kinetic theory of gases, which has been revived since 1824 by Herapath, Joule, and Krönig, and developed chiefly by Clausius and Clerk Maxwell.

The law of Boyle and of Mariotte follows as a natural consequence of this idea. Suppose a gas occupying a certain volume, and composed of a definite number of material particles —or molecules so-called—to be contained in a closed vessel, such as the cylinder of an air-pump; the pressure on the piston will be determined by the number of shocks of the molecules diffused through the neighbouring stratum of gas. If, then, the volume of the gas be reduced, the number of particles in this layer will be increased, as well as the sum of the shocks, and the pressure will be increased in proportion thereto.

The velocities with which these molecules move are enormous. Clausius supposes that the molecules of air move with a mean velocity of 485 metres per second, and those of hydrogen with a mean velocity of 1844 metres per second. I say mean velocity, for all the particles of a gas do not move at the same rate. But can the particles freely traverse these wide spaces? By no means; their number is so immense, that at every instant they enter into collision with one another, and rebound in such a manner that their motion is altered both in velocity and in direction. It follows, therefore, that the molecules of a gaseous mass are continually moving in all directions with variable velocities, their motion in the intervals between the collisions being sensibly rectilinear. The distribution of the velocities has been made the subject of important researches by Clerk Maxwell.

These movements of gaseous molecules determine a very important physical condition, namely, temperature. In fact, the energy of the rectilinear movements, that is to say, the mass of the gaseous molecules multiplied by the square of their velocity, gives the measure of the temperature, which consequently increases proportionally to the energy of the rectilinear movement, or, for the same gas—since the masses remain constant—it increases as the square of the velocity. If the velocity were reduced to nothing, the calorific motion would be annihilated, that is to say, the gas would be entirely deprived of heat. This state corresponds with the absolute zero.

The gaseous molecules moving in all directions and coming into collision with one another in space, are very nearly emancipated from cohesion. Nevertheless this attractive force makes itself felt for the infinitely short time during which the molecules actually touch one another, or are on the point of doing so. This influence of cohesion is one of the causes of deviation from the law of Boyle or of Mariotte.

In liquids the influence of cohesion is manifest, preventing the molecules from separating, though it allows them to glide one over the other. This molecular cohesion, or attraction, is in continual strife with the force of expansion, or kinetic energy, which, if unopposed, would launch the molecules into space.

To understand the antagonism between these two forces, consider for a moment a saturated vapour in contact with the liquid from which it has been formed. When it is reduced to a smaller volume, a certain number of its molecules are brought within the sphere of action of cohesion; they are consequently aggregated together and precipitated in the liquid state, while the rest, being

now diffused through a wider space, continue to move with the same velocity and to exert the same pressure as before. In this case the force of cohesion of the liquid particles exactly balances the expansive force or kinetic energy, and serves to a certain extent as a measure of its amount.

Now let the vapour be heated, after it has been withdrawn from the action of the liquid; its expansive force will then increase; it will dilate, and may then be compressed, until, by the approximation of its particles, it is again brought within the sphere of action of the cohesive force, that is to say, to the point of saturation corresponding with the temperature to which it has been raised. With the increase of temperature, the expansive force or kinetic energy of the vapour likewise increases, whereas the cohesion of the liquid becomes less: hence the necessity of further diminishing the distances between the particles by increase of pressure. But this double effect of increased kinetic energy of the gaseous molecules, and diminished cohesion of the liquid molecules, going on progressively as the temperature rises, a point will at length be attained at which the energy of the molecular movement will finally gain the victory over the force of cohesion, *whatever be the pressure to which the vapour is subjected*. The minimum temperature at which this effect is produced, and at which, therefore, a vapour can no longer co-exist with its liquid under any pressure whatever, has been called by my friend, Dr. Andrews, the critical point, and by M. Mendelejeff, the absolute boiling point. Above this temperature, whatever may be the pressure, the gas, whether dilated or compressed, will maintain the same physical state, characterised by freedom of molecular or calorific movement.

I can show you by an experiment this peculiar phenomenon of the sudden passage of a liquid mass to the state of gas, by heating liquid carbonic acid in a closed vessel, just as Cagniard de Latour formerly heated ether. Here is a tube, half filled with liquid carbonic acid, which we are about to immerse in water at 35°; you observe that the liquid first rises quickly in the tube, its coefficient of expansion being greater than that of gases; at the same time the meniscus flattens more and more, indicating a diminution of cohesion in the liquid (Andrews), and finally disappears altogether; in fact the liquid itself has disappeared, having been entirely and suddenly transformed into gas. What now must we do to cause it to reappear? We must lower the temperature, so as to diminish the kinetic energy of the gas, and increase the cohesion of the liquid. A moment will then arrive when the cohesive force will again be able to resume the contest, and the liquid will be reconstituted.

We are now in a position to understand why certain gases, hitherto called *permanent*, cannot be liquefied except by the combined action of very strong pressure and a very great degree of cold. The critical points of these gases are situated at very low temperatures. They have quite recently been liquefied, this great discovery having been made by MM. Cailletet and Raoul Pictet.

The principle of Cailletet's apparatus is the following:—The gas to be liquefied is introduced into a cylindrical glass vessel and transferred by means of mercury to a very strong glass tube sealed into the reservoir. This latter is firmly fixed in a cylindrical cavity hollowed out of a block of iron, and serving as a kind of closed mercurial trough. The cylindrical cavity communicates with a hydraulic press which injects water on to the surface of the mercury, driving it into the gas reservoir, which is ultimately quite filled with that liquid, the gas being thereby driven into the tube, where it is liquefied.

In this manner we shall be able by a few strokes of the piston of the hydraulic press to liquefy carbonic acid. Other gases less easily condensable may be liquefied in a similar manner, if the tube be cooled to – 20° or – 30°. But these temperatures do not suffice for the liquefaction of the so-called permanent gases. To cool these gases to lower temperatures, M. Cailletet avails himself of sudden expansion (*détente*). The gas, compressed to several hundreds of atmospheres, when allowed to expand suddenly and drive the air before it, consumes a certain quantity of heat, and is thereby reduced to a kind of mist, which will appear on the screen, and pass away like a cloud, if we suddenly expand the strongly compressed carbonic acid gas, which we have here, in default of oxygen or hydrogen.

M. Raoul Pictet has succeeded in condensing oxygen and hydrogen in the form of liquids, properly so called, and even in obtaining the latter of these gases in the solid state. To produce this effect, he employs condensing apparatus of incomparable power, combining the action of a cold of 120° to 140° below zero with that of enormous pressures amounting to 550 and even 650 atmospheres. The pressure is produced by the accumulation of the gases in a closed space consisting of a long copper tube of very thick metal. The oxygen was produced by heating potassium chlorate in a howitzer shell, having a copper tube soldered into its orifice. The hydrogen was prepared in a similar apparatus, by decomposition of a dry mixture of potassium formate and potassium hydrate.

To produce very low temperatures of 120° or even 140° below zero, M. Pictet resorts to a very ingenious artifice. Over the reservoir-tube which surrounds the copper tube, and in which these low temperatures are intended to be produced, he superposes another system of concentric tubes, intended to produce a first fall of temperature amounting to – 65°, by the volatilisation of liquid sulphurous acid. By means of this first depression of temperature it has been found possible to liquefy carbonic acid gas in the inner tube of the system just mentioned, by a pressure of only a few atmospheres. The carbonic acid thus liquefied being introduced into the lower reservoir-tube of the apparatus, produces by its volatilisation, a second fall of temperature round the copper tube containing the compressed oxygen which is to be liquefied. M. Pictet has in fact established a double circulation, one of sulphurous acid, the other of carbonic acid. I will describe the former. Sulphurous acid gas is liquefied by a pressure of three atmospheres and collects in a strong vessel, from which it passes through a tube into the upper reservoir. The pressure is exerted by means of a force-pump. A suction-pump connected with the force-pump, and acting in concert with it withdraws the liquid sulphurous acid from the reservoir-tube, and transfers it to the force-pump, which brings it back to the vessel, and thence to the upper reservoir-tube.

The circulation of the carbonic acid is established in the same manner, by means of two pumps, one of which condenses the gas by forcing it into tubes cooled to – 61°, while the other, which is a suction-pump, sends it back to the force-pump. The volatilisation of the carbonic acid produces round the copper tube the low temperatures above-mentioned. The copper tube is in fact surrounded by solid carbonic acid.

In this manner M. Pictet has liquefied oxygen, and has approximately calculated its density. He has also liquefied and even solidified hydrogen, which he has seen to issue from the tube in the form of a steel-blue liquid jet, which partly solidified. The solid hydrogen, in falling on the floor, produced the shrill noise of a metallic hail, thus confirming the bold and ingenious idea of Faraday, who first suggested that hydrogen is a metal.

The experiments of MM. Raoul Pictet and Cailletet have then removed from science the distinction between permanent and condensable gases. Permanent gases exist no longer. All aeriform fluids may be liquefied with a facility greater in proportion as their critical points are situated at higher temperatures. From a physical point of view, therefore, gases and vapours have the same constitution, being formed of molecules which move freely in space. In what, then, do they differ? They differ by the nature and constitution of these molecules; and here we enter on the domain of CHEMISTRY.

It is supposed, in chemistry, that the molecules of each species of gas or vapour are formed of a definite number of atoms. The simplest molecules, like those of mercury-vapour, are formed of single atoms. Others include several atoms of the same or of different kinds: and these latter molecules may be very complex, that is to say, formed of a large number of atoms held together by affinity, and vibrating in concert in a system to which they are attached, viz., the molecule. In this system, which has a definite form, extent, and centre of gravity, the molecules execute their own proper movements, and are at the same time carried forward with the entire system in the molecular paths.

I cannot here dilate on the nature and chemical properties of the several gases and vapours. I wish merely to throw light on a single point, which is of great importance, inasmuch as it constitutes one of the foundations of chemical science.

The proposition which I am about to enunciate is generally adopted by chemists, resting as it does on an imposing array of facts: *Equal volumes of gases or vapours, under the same conditions of pressure and temperature, contain equal numbers of molecules.*

The Italian chemist, Amadeo Avogadro, in discussing the discoveries of Gay-Lussac respecting the simple relations which exist between the volumes in which gases combine, was the first to recognise that there likewise exists a simple relation between the volumes of gases and the number of molecules which they contain. The simplest hypothesis, said he, that can be made regarding this matter consists in supposing that all gases contain in equal volumes equal numbers of "integrant molecules." By this term he denoted what we now call simply *molecules*, and he distinguished these integrant molecules from the "elementary molecules" which we call *atoms*. According to him the integrant molecules of gases are all equally distant one from the other, and these distances are so great in proportion to the dimensions of the molecules, that the mutual attraction between the latter is reduced to nothing.

These integrant molecules are composed of a greater or smaller number of elementary molecules, not only in compound, but likewise in simple bodies; the integrant molecules of chlorine, for example, are composed of four elementary molecules, and the same is the case with the integrant molecules of hydrogen. What happens, then, when chlorine and hydrogen combine together? The integrant molecules of these two bodies are then resolved into elementary molecules, which combine, two by two, to form hydrochloric acid.

Ideas analogous to those of the Italian chemist were enunciated in 1814 by Ampère, and thus there has been introduced into chemical science the notion that there exist two kinds of small particles, namely, molecules and atoms, the former being diffused in equal numbers through equal volumes of gases.

But this notion, so clearly enunciated more than sixty years ago, was afterwards destined to be obscured. Berzelius, taking up Ampère's proposition, altered it by substituting atoms for molecules, and saying that "equal volumes of gases contain equal numbers of atoms." This proposition, which has given rise to long discussions, must now be rejected, for it is inexact. It is to Gerhardt, and more recently to Cannizzaro, that is due the honour of having restored the thesis of Avogadro and Ampère, and pointed out its importance in connection with chemical theory. This I must explain in conclusion.

In the first place Gerhardt simplified the rule of Avogadro. The latter supposed that a molecule of chlorine or of hydrogen contains four atoms, whereas Gerhardt regards it as consisting of two. Avogadro's proposition thus modified, assumes a very simple form, and may be enunciated in the following terms. Suppose that a volume, or the unit of volume, of hydrogen contains one atom; then the molecules of all gases and vapours will occupy two volumes. Thus, a molecule of hydrogen formed of two atoms will occupy two volumes, and a molecule of chlorine formed of two atoms will likewise occupy two volumes. What now will happen when chlorine combines with hydrogen? The molecules will be cut in two, and each of the two chlorine-atoms uniting itself to an atom of hydrogen, two molecules of hydrochloric acid will be formed, each occupying two volumes. Thus if an atom of hydrogen occupies one volume, a molecule of hydrochloric acid will occupy two volumes. The same is the case with the molecules of all other gases and vapours.

A molecule of water formed of 2 at. H and 1 at. O occupies 2 volumes.
" ammonia " 3 at. H and 1 at. N " "
" marsh gas " 4 at. H and 1 at. C " "

This list might be prolonged by taking as examples a large number of gaseous or volatile bodies belonging both to mineral and to organic chemistry, and including chlorinated, brominated, and oxygenated compounds of the metalloids, and of a large number of metals. The countless volatile compounds of organic chemistry, hydrocarbons, alcohols, chlorides, bromides, organo-metallic compounds, compound ammonias, aldehydes, ketones—all this legion of various compounds—conform to the law of Avogadro and Ampère, their molecules occupying two volumes if an atom of hydrogen occupies one volume. Hence it follows that the relative weights of two volumes represent the relative weights of the molecules, or the molecular weights. To find these latter, therefore, it is sufficient to double the numbers which express the weights of a single volume, or of the unit of volume, that is to say the densities. The densities of gases may be referred to that of hydrogen as unity, and the atomic weights to that of hydrogen. The unit being then the same, it follows that the numbers which express the double densities referred to hydrogen will also represent the molecular weights.

Chemists represent the constitution of molecules by formulæ, each of which shows the number of atoms condensed within the molecule. Now the molecular weights being known, it is very easy to deduce the formulæ from them, as these formulæ must represent the number of atoms comprised in two volumes. Such is the relation which exists between the Law of Volumes and Chemical Notation. The rule of Avogadro and Ampère has, in fact, become one of the bases of this notation. There are, however, certain exceptions to its generality, but they are probably more apparent than real. Sal-ammoniac, ammonium sulphhydrate, phosphorus pentachloride, iodine trichloride, sulphuric acid, calomel, amylene hydrobromide, and chloral hydrate, have vapour-densities such that their molecules appear to occupy four volumes. Such, however, is not the case; and it may be shown that the bodies in question do not volatilise without decomposition, but that, when they are heated, their molecules split up into two, each of which occupies two volumes. Being unable to analyse all the cases above-mentioned, I will confine myself to the last, viz., chloral hydrate, which has given rise to a long discussion.

The question to be decided is, whether this compound is or is not decomposed by conversion into vapour? If it really suffers decomposition, it should be resolved into anhydrous chloral and water. That this decomposition really takes place may be shown by a method based on the theory of dissociation developed by M. H. Sainte-Claire Deville.

Here is the case in a few words. We have here in a tube a certain volume of the vapour of chloral hydrate under a certain pressure; it is required to show that this vapour contains vapour of water. For this purpose we are about to introduce into it a body capable of emitting vapour of water, crystallised potassium oxalate, for example. If the atmosphere is dry, this salt will give off vapour of water just as it would in dry air or in vapour of chloroform at the same temperature, and it will continue to emit this vapour until the atmosphere shall have taken up a degree of humidity corresponding with that which is designated by M. H. Sainte-Claire Deville the *dissociation tension* of the hydrated salt in question. If, on the other hand, the chloral atmosphere is moist, and exhibits exactly the degree of humidity just defined, the crystallised oxalate will not emit any water. In this first tube, then, we have the vapour of chloral hydrate; the second contains vapour of chloroform. This latter is dry, and I am about to prove to you that the former is moist. In fact, the crystallised potassium oxalate which we are introducing into the chloroform tube will rapidly depress the level of the mercury by emitting vapour of water, whereas in the atmosphere of chloral hydrate it will not emit vapour of water, and consequently will not depress the level of the mercury. This shows that chloral hydrate undergoes decomposition when converted into vapour, and this supposed exception to the rule of Avogadro and Ampère vanishes, like all the rest, when submitted to the test of experiment. This rule appears, then, like a grand law of nature, as simple in its enunciation as it is important in its consequences.

Such are the considerations which I wished to lay before you on the physical and chemical constitution of gases. Does not this exposition seem to show that, of all the states which matter can assume, the gaseous state is the most accessible to our researches, and the best known—not, indeed, that we can affirm the certainty of the theoretical considerations which I have brought before you, for they are but probable. In the physical sciences nothing is certain but well-observed facts and their immediate consequences; and, whenever we attempt to make these facts the basis of any general theory, hypothetical data are apt to mix themselves up with our deductions. In the present case the hypothesis consists in assuming that gases, and matter in general, are formed of molecules, and these latter of atoms. No one has ever seen these molecules and atoms, and it is certain that nobody ever will see them. Does it follow then that we ought to reject or disdain this hypothesis? By no means. Our theories may be verified in their consequences, and may thereby acquire a certain degree of probability. The theory under consideration has been subjected to this ordeal, and nothing has hitherto been found to contradict it. It is probable, indeed, that gases are composed of small particles moving freely in space, with immense velocities, and capable of communicating their motion by collision or by friction. It is probable that these molecules are diffused in space in numbers so enormous that the most rarefied spaces still contain legions of them; and it is this circumstance which explains the possibility of the movements of the radiometer.

Be this as it may, the idea of Daniel Bernoulli has been developed into a beautiful theory—the kinetic theory of gases—a theory which has shed a sudden clearness, an unexpected light, on matters which seemed to be veiled in the deepest obscurity. The molecules, as already stated, are invisible. Nevertheless, attempts have been made to pene rate this invisible world by the force of scientific reasoning, and by an effort which does honour to the human mind, even if it be destined to remain barren. The illustrious authors of the kinetic theory of gases have sought to determine, not only the velocities of the gaseous molecules, and the prodigious number of their collisions during a unit of time, but likewise their distances, their absolute dimensions, and their number in a given volume. And here we arrive at results which bewilder the imagination, but which, in this lecture, I must not attempt to unfold.

Permit me only to add that these great labours mark a resting place in our course, and are, perhaps, an approach towards the solution of the eternal problem of the constitution of matter—a problem which dates from the earliest ages of civilisation, and though discussed by all the great thinkers of ancient, as well as of modern, times, still remains unsolved. May we not hope that in our own time this problem has been more clearly stated and more earnestly attacked, and that the labours of the nineteenth century have advanced the human mind in these arduous paths, more than those of a Lucretius, or even of a Descartes and a Newton. From this point of view, the discoveries of modern chemistry, so well expressed and summarised by the immortal conception of Dalton, will mark an epoch in the progress of the human mind; and to one of the most important among these discoveries—that of the liquefaction of the gases—grateful posterity will for ever join the glorious name of FARADAY.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

BIOLOGISTS will be pleased with the frank recognition of Dr. Foster's services contained in the statute proposed by the Council of the Senate at Cambridge for the new Professorship of Physiology to be founded by Trinity College. It is to be permanently recorded that Dr. Foster's lectures have always been open to the entire University, and that he "has successfully promoted" the study of physiology. Thus the continued self-denying effort and enthusiasm which have in eight years developed a school of over seventy students, and which have called forth the original talents of a score of ardent young investigators, will find still fuller scope. We understand that Dr. Foster resolutely declined to sanction any arrangement by Trinity College to secure for him the first tenure of the professorship, preferring to leave the University perfectly unfettered in its choice. But the Council of the Senate, which is a thoroughly representative body, chooses to signify the inseparable connection of the work with Dr. Foster's name by the very wording of the statute. The professor is to be elected by a board consisting of the Vice-Chancellor, of four members nominated by the Council, and four nominated by the Board of Natural Science Studies. One of each four must be neither resident in the University nor officially connected with it.

THE Cambridge mechanical workshops, organised by Prof. Stuart, bid fair to become of importance to research in the country generally, as well as in Cambridge. Prof. Stuart, on his own responsibility, has completely fitted up the workshops with all machinery necessary for the construction of philosophical apparatus. He has engaged a number of the most competent workmen as teachers, and to construct apparatus required by professors and investigators who are often deterred from researches because of lack of appliances or time to make what they want. Classes are formed for the regular instruction of university men in the use of tools and the construction of machines, and these are attended at present by a dozen students, several of whom intend to become engineers.

MR. A. C. HADDON, of Christ's College, has been nominated by the Board of Natural Sciences Studies, Cambridge, to study at the Zoological Station at Naples during the ensuing season.

DR. GREENFIELD, of St. Thomas's Hospital, has been appointed by the Senate of the University of London to succeed Dr. Burdon Sanderson as Professor of Comparative Pathology at the Brown Institution.

THE subscriptions already received or promised for the extension of the buildings of University College, London, amount to upwards of 14,000*l.*

BY the will of the late Mr. Charles Randolph, engineer, 60,000*l.* has been left to the building fund of Glasgow University.

THE third annual report of the Johns Hopkins University, Baltimore, issued by President Gilman, is of the highest interest, and shows that the attempt to establish a purely philosophical university has been eminently successful. Our readers are no doubt familiar with the principles on which this institution has been based. It was not sought to add one more to the many colleges already existing in the United States, but to found a genuine university in which those who had the inclination and the capabilities would have every facility for carrying their elementary or collegiate studies into the region of research in the various departments of human knowledge. The method of work has been carefully planned; the best men obtainable have been got to superintend the work of the students, who are admitted only on showing that they are really able and willing to pursue the courses which have been arranged. It is a many-sided and active centre of the highest learning, and cannot but have an invigorating result on science in all its departments in the United States. We would recommend those of our readers interested in the higher education to procure a copy of this report, which deserves a more detailed notice than we have space for.

THE Budget for Public Instruction will be deposited this week in the Bureau of the French Chamber of Deputies. A large increase is asked for in favour of public instruction. The credit granted will exceed two millions sterling. In 1823 it was only two thousand pounds, consequently in a little more than half a century it has been multiplied a thousand-fold. M. Bardoux will propose the creation in each department of a high school for popular education according to the models which have proved so successful in Paris. The benefit of the organisation realised in the capital will be extended to the whole of France if the scheme of the active minister is adopted, as will most probably be the case.

AT Stockholm the "Free" University was opened on October 14 last. The funds collected for its foundation now reach the sum of 820,000 Swedish crowns. It is intended to establish a similar university at Gothenburg.

SCIENTIFIC SERIALS

The American Journal of Science and Arts, October.—Besides two valuable papers by Professors Mayer and Draper, reproduced in our columns, we have here an account of the curious artificial mounds of North-Eastern Iowa, by Mr. McGee. They consist of tumuli, smaller conical mounds, embankments, and animal mounds, and from numerous measurements the builders seem to have used a unit which either was, or grew out of, the pace or yard. A slow southerly migration of the mound-builders is supposed to explain the evident increase in geometrical knowledge attested by various works found in passing across the United States from north to south.—Prof. Young furnishes details of observations of the Princeton Eclipse Expedition.—The flour-mill explosion at Minneapolis in May was probably due to the running dry of a set of stones which ground middlings, one of six sets discharging into a spout which communicated with a dust-house. Mr. Peckham studies the case, pointing out that there is greater danger with middlings, because it is dryer, and is ground at a higher temperature, and finer. The dry stones may heat the last part of the grist remaining, sufficiently to make it like tinder, so that it readily ignites on receiving a spark from the stones. The practical problem is how to prevent or detect dry stones, especially those for middlings.—Mr. Becker indicates the *rationale* of correction for vacuum in chemical analysis.—Prof. Smith writes on the composition of the new meteoric mineral, Daubreelite, and its frequent, if not universal, occurrence in meteoric irons.—Prof. Watson gives a more careful determination (than previously) of the intra-Mercurial planets.

Annalen der Physik und Chemie.—No. 9, 1878.—The excitation of electricity on contact of solid and gaseous bodies, forms the subject of an opening paper by Herr Beetz, who thinks the case is either one of differences of tensions produced by different conducting liquids, or of change of metals by gases which have ceased to be in the gaseous state, either through occlusion in the metals, or condensation on their surface.—From experiments on production of

galvanic currents by streaming of liquids through tubes, Herr Dorn infers that the motion of the liquid in itself produces no considerable part of the electromotive force observed; the influence of the tube wall, on the other hand, is undoubted.—Herr Wiedemann shows that an examination of magnetic behaviour of iron oxide salts is well adapted for determining with accuracy, even quantitatively, their dissociation in solutions at different temperatures, the conditions of their fixation by acids, and their exchange with other salts.—In the first portion of an inquiry into the divergences of some gases from Boyle's law at 0° and 100°, Herr Winkelmann gives an interpolation formula, expressing this divergence in the case of ethylene.—A new proposition in the theory of diffraction proved by Herr Frölich, is, that with small angles of diffraction, the kinetic energy of the incident light for an aperture of any shape is equal to the kinetic energy of the diffracted light.—Some experiments on the nature of the phases and change composition in telephonic transmission are described by Herr Hermann.—There are also notes on the relation between refraction equivalent and wave length, and on excitation of electricity by pressure and friction.

Journal of the Franklin Institute, October.—This contains a short account by Prof. Henry Draper, of his eclipse observations at Rawlins, Wyoming Territory, together with a photograph of the corona, showing the unequal distribution of its matter in the plane of the ecliptic and ray-like forms towards the poles of the sun.—Mr. Bell furnishes an account of the now historic "Camel" locomotive engine of Ross Winans, built in June, 1848. It first practically demonstrated the superiority of the eight-wheel connected engine for heavy traffic; it had also an inclined firebox, and other features of novelty.—The new system of electric lighting by Profs. Thomson and Houston, is described, consisting in causing one or both the carbon electrodes to vibrate to and from each other, so that the effect of the light produced is continuous. This allows of a feebler current being used.—Mr. Isherwood analyses some Scotch experiments on economic vaporisation of water and expansion of steam.

SOCIETIES AND ACADEMIES

London

Linnean Society, November 7.—Prof. Allman, F.R.S., president, in the chair.—Sir Joseph D. Hooker, C.B., presented to the Society, in the name of a committee of gentlemen, a portrait of the Rev. M. J. Berkeley. A great matted mass in sheet of a Chara (*Nitella* sp. ?) was exhibited by Dr. Thos. Boycott. It had been got from a dried-up pond in St. Leonard's Forest, Sussex, June, 1877; within its meshes many interesting microscopic forms were obtained.—Mr. Thos. Christy next called attention to living specimens of West African indian-rubber trees, the *Urostigma Vogelii*, and another undetermined species recently arrived. He likewise showed the fruit, flower, and leaf in spirit, with a dried ball of the gum of the commercially valuable *Landolphia florida*.—Dr. Maxwell Masters read an extract from a letter of Dr. Beccari describing a gigantic Aroid found by him in Sumatra, side by side with the *Rafflesia arnolii*. The species has a large tuber 5 feet round, from which is pushed up a single leaf, with a long, stout petiole, the divided blade covering an area of 45 feet, or 15 metres.—Dr. R. C. A. Prior showed a specimen of *Colletia cruciata* in blossom, grown out of doors in Somersetshire by the Rev. W. Sotheby.—"Notes on Euphorbiaceæ," by Mr. G. Bentham, read in title, was a paper treating of the history, nomenclature, systematic arrangement, and the origin and geographical distribution of this remarkable order of plants. Among Dicotyledons, Euphorbiaceæ stands fourth in point of numbers, having above 3000 species and 200 genera. In investigating the origin of the order the geological record, unfortunately, is of no assistance. Their evident, generally tropical nature, is a striking feature, and, judging from various data, it is conjectured that their most ancient home was in the old world. Their affinities have repeatedly been discussed by botanists, but though there are individual genera which may exhibit some one character supposed to ally to other orders, yet no real connection has hitherto been pointed out. Their isolation is produced, not so much by any one special character, as by a special combination of several. As to position in the linear series, unless the order be broken up, practically it must remain among the Monochlamydeæ, in spite of occasional presence of corolla in some forms. The author has a most interesting chapter on nomenclature and synonymy, well worthy the study and serious attention of biologists generally.—Mr. Lewis A. Bernays, in a letter to the secretary, records the undoubted existence of *Carpesium cernuum*, in Queensland, and suggests its being indigenous there.—In a paper given in abstract, "Descriptions of New Hemiptera," by Dr. F. Buchanan White, the diagnosis of 2 new genera (*Helenus* and *Neovelia*) and 17 new species are entered. These mainly are the results of Prof. Trail's late exploration of the regions bordering the River Amazon.—Mr. Alfred W. Bennett read a communication, "Notes on Cleistogamic Flowers; chiefly of *Viola*, *Oxalis*, and *Impatiens*." According to him there are two kinds:—(1) Those which hardly differ from the perfect open flowers, other than the partial or entire suppression of the corolla, and the closing of the calyx (= homocleistogamic); and (2) those with a distinct modification in the flower to aid self-fertilization (= heterocleistogamic). He was at first disposed to regard those two kinds as having arisen, one by degradation, the other by a rudimentary form of the organ: but subsequent examination convinced him that both kinds owe their origin to degradation. In the extreme cleistogamic flowers a large number of organs have been correlatively modified. Most interesting phenomena occur in the mode of emission of the pollen tubes, these travelling through the air in a straight line from the anther vertically upwards in *Oxalis*, horizontally in others, and creep along the surface and even back of ovary in *Viola canina*. An unseen agency directs, for none wander with uncertainty; and this is all the more remarkable because, when not in proximity to the stigma, the pollen grains protrude their tubes in all possible directions.—The Rev. G. Henslow orally delivered the gist of a paper "On the Absorption of Dew and Rain by the Green Parts of Plants" (*vide Science Notes*).—The Rev. W. W. Fowler and Messrs. Wilfred Huddlestone and T. M. Shuttleworth were elected Fellows of the Society.

Chemical Society, November 7.—Dr. Gladstone, president, in the chair.—The following papers were read:—Contributions from the Laboratory of Tôkio, Japan. On the red colouring matter of the *Lithospermum erythrorhizon*, by M. Kuhara. The purple colouring matter was prepared from the root by extracting with alcohol, purifying by treatment with lead acetate, &c.; it forms a dark, resinous, uncrystallizable mass, with a metallic green reflection, soluble in alcohol, ether, benzol, almost insoluble in water; it resembles in some respects anchurin, the colouring matter from alkanet. A bromine and a chlorine compound were prepared.—A second report on some points in chemical dynamics, by C. R. A. Wright, and A. P. Luff. The authors have continued their previous research and have determined the temperature of initial action of carbonic oxide, hydrogen, and carbon on various oxides of iron, manganese, lead, cobalt, and nickel. They find that the general law holds good, that the temperature of the action of carbonic oxide lies below that of hydrogen, which again is below that of carbon; this rule appears to be a special case governed by the general law that *cæteris paribus* the greater algebraically is the heat evolution taking place during a reducing action on a metallic oxide, the lower is the temperature at which the action is first noticeable during a few minutes' action.—Note on the constitution of the olefine produced by the action of zinc upon ethylic iodide, by Dr. Frankland and Mr. Dobbin. The gas given off was passed through a cohol and sulphuric acid, and then absorbed by antimonic chloride; on heating with water and distilling a chloride was obtained, boiling at 83° C.; it was therefore ethylenic, and not ethylidenic chloride.—On the occurrence of certain nitrogen acids amongst the products of the combustion of coal gas and hydrogen flames, by L. T. Wright. The author proves that the origin of the nitrogen acids found in the condensed water procured by burning coal gas or hydrogen in the air is ammonia, either free or combined, no such acids being produced when the gases are carefully freed from ammonia.—On the action of bromine upon sulphur, by J. B. Hannay.—Researches on dyeing. Part I. Silk and rosanilin, by Dr. Mills and Mr. G. Thomson. The authors have investigated the nature of the transaction which occurs when a vat is exhausted of its tinctorial ingredients. The experiments consisted in immersing a constant area of white silk in a solution of a rosanilin salt at a constant temperature for varying times, and then determining the loss of strength of the rosanilin solution.—Comparison of the actions of hypochlorites and hypobromites on some nitrogen compounds, by H. J. H. Fenton. The compounds selected were, ammonium carbamate, guanidine, and biuret.—Notes on two new vegeto-alkaloids by

F. von Müller and L. Rummel. The authors have prepared alstonin from the bark of alstonia constricta, and duboisin from the leaves and twigs of duboisia myoporoides; the latter closely resembles piturin.—On the determination of lithia by phosphate of soda, by C. Rammelsberg. The author confirms his previous results as to the formation of a double salt of sodium and lithium phosphate and the consequent inaccuracy in lithia determinations made by Mayer's method; he also gives some analyses of lithia micas.

Physical Society, November 9.—Prof. G. C. Foster, vice-president, and afterwards Prof. W. G. Adams, president, in th- chair.—The following candidate was elected a Member of the Society:—Sir Frederick Elliot.—Prof. W. G. Adams explained a simple appliance made by Mr. S. C. Tisley for exhibiting the coloured bands due to interference with thick plates. The bands due to regular reflection and refraction were produced by two thick plates nearly parallel to each other and fixed in a brass box with rectangular apertures on its flat faces so that the light fell on the first plate at an angle of 60°, the whole apparatus being of a convenient size for the waistcoat pocket. On a previous occasion (June 23, 1877), Prof. Adams exhibited these bands to the Society, but not in a portable form. The elliptical interference bands, due to the scattering or diffusion of light at a point on the front surface of one of the plates, were shown by means of a precisely analogous arrangement, except that the inclination of the plates to each other was somewhat greater; in this case the interference bands, formed by *regular* reflection and refraction, fall in another direction, so that they are not received by the eye; the diffusion interference fringes obtained were clearly visible when thrown on the screen. They are formed by rays once diffused from points on the first surface and afterwards regularly reflected and refracted from the front and back faces of the two plates in succession. Prof. Adams pointed out that this instrument would form a convenient means of obtaining polarized light in cases where the length of a Nicol's prism is objectionable, for instance, under the stage of a microscope; the light will be completely polarized if the plates be placed to receive the light at the polarizing angle, and the field will be much brighter than when a plate of tourmaline is employed.—Prof. W. F. Barrett exhibited and explained Edison's microtasimeter and carbon telephone. These have been recently described in NATURE. In the course of a brief recapitulation of the history of these instruments, he referred to Du Moncel's early observations, published in 1856, that variations in the resistance of a circuit can be produced by varying the pressure on metallic surfaces in contact, and after referring to Clérac's plumbago rheostats he stated that Edison was probably the first to apply the diminished resistance of carbon under pressure to a practical use, which he did early in 1877 in his carbon relay, the progenitor of the carbon rheostat, micro-tasimeter and carbon telephone. In all he uses compressed lampblack, a button of which may be formed as follows. The wick of a paraffin lamp having been cut so that it smokes, a quantity of lampblack is formed in the chimney; the lower portion, which has the more intense black colour, is collected from time to time, and all brown particles must be carefully removed, since they offer a greater resistance. The mass is compressed into a disc about the size of a sixpence, crushed, passed through a fine sieve, and again compressed, and this operation may be two or three times repeated in order to attain to perfect uniformity. The original form of tasimeter, in which the hard rubber or other substance was placed horizontally, has been modified so that the whole is vertical. The carbon button rests on a smooth metallic surface in connection with a binding screw, and a similar conducting surface rests upon it leading to a second binding screw. A strip of hard rubber 1 inch long, $\frac{1}{4}$ inch wide, and $\frac{1}{16}$ inch thick, is supported vertically above it, its upper end being attached to a fine screw worked by a tangent screw with graduated head. The whole is inclosed in a heavy conical brass box. Prof. Barrett suggested that it would be preferable to make this jacket cylindrical, and that the whole should be inverted, because the weight of the strip on the button is found to prevent the needle of the galvanometer returning at once to zero. Employing one Daniell's cell and inserting a shunt, Wheatstone's bridge, and resistance coils in the circuit, it was shown that the hand, at some distance, caused a considerable deflection, and Prof. Barrett stated that in a still room the instrument becomes so sensitive as to be almost unmanageable. By replacing the hard rubber by a strip of gelatine varnished on one side, a very slight change in the hygrometric state of the atmosphere can be detected by the absorption of moisture causing expansion of the gelatine, and, therefore, compression of the carbon. Its action as an aneroid baroscope was suggested by Prof. Barrett, the button being associated with an exhausted box. He pointed out that before the tasimeter can be used as a measuring instrument, experiments must be made in order to ascertain the exact relation between the resistance of carbon and the pressure to which it is subjected. The carbon telephone, full particulars of which will be found in NATURE, vol. xix. p. 12, was next described, and Mr. Adams, Mr. Edison's assistant, now in England, exhibited a complete transmitting apparatus, with call, &c. A very ingenious and simple form of shunt, received from Mr. Edison with the tasimeter, deserves mention. A row of brass studs fixed on a board are united by plugs, so that if the current enters at one end it can pass out at the other without meeting with any appreciable resistance. But if a plug be removed it throws in about 4 inches of a resisting wire wound over two rows of pins, underneath the board, one row of which is in metallic connection with the studs; thus the entire length of wire is in circuit when all the plugs are removed. Finally, Prof. Barrett mentioned that a communication has just been received from Mr. Edison stating that he has succeeded in arranging an efficient receiving instrument in which no form of magnet is employed.—Mr. Ladd then showed several forms of electric lamp arranged so as to render the use of clockwork unnecessary. In that known as Wallace's workshop lamp the spark passes between the edges of two plates, the lower one being fixed while the upper one is raised to a suitable distance by an electro-magnet brought into action immediately on the passing of the current. A second form, in which an annular magnet was employed, acted on the same principle, the armature carrying the upper plate being specially arranged so as to give a maximum of attractive force. In the third form, the V-lamp, two rods of graphite were inclined at an angle of 45° to the vertical, resting in contact on a piece of china. Immediately on the current passing an electro-magnet is caused to act, and, after the rods have been firmly gripped, they are separated and the support removed. Should the circuit be broken they will at once fall together.

VIENNA

Imperial Academy of Sciences, October 10.—The deaths of Dr. Rokitansky and Prof. Tomaschek were referred to.—The following among other papers were read:—The dolomite ridges of South Tyrol and Venetia (Heft 2 and 3), by Dr. Mojsisovics.—On electric penetration of glass, by Prof. Mach.—On the relation of diffusion-phenomena to the second proposition of the mechanical theory of heat, by Prof. Boltzmann.—Calorimetric research on the heat of combination of carbonic acid gas and ammonia gas, to carbonate of ammonia, by Herr Lecher.—Action of radiant heat of the sun on a body in shade—time of occurrence of maximum temperature, by Herr Schlemüller.—Description of a telescope, by means of which, with one objective, you may point on two objects simultaneously, one distant, the other near, (sealed packet) by Herr Schneider.—Physical experiments, by Dr. Gross.—Distance reflector with precision-reading, by Herr Kuczera.—Discovery of a comet, by Mr. L. Swift.—Meteorite fall at Tieschitz in Mähren, July 15 last year, by Herr Tschermak.—Development-history of the prothallium of *Scolopendrium vulgare*, Sym., by Dr. Beck.

THURSDAY, NOVEMBER 28, 1878

RAMSAY'S MANUAL OF BRITISH GEOLOGY

The Physical Geology and Geography of Great Britain: A Manual of British Geology. By A. C. Ramsay, LL.D., F.R.S., &c., Director-General of the Geological Surveys of the United Kingdom. Fifth Edition. (London: Edward Stanford, 1878.)

THIS well-known work has now reached its fifth edition, and has undergone such changes that it may be almost regarded as a new book. Not only has the quantity of matter in it been almost doubled since the last edition, and its bulk and price augmented in the same proportion, but its plan has been very greatly modified, as is indeed indicated by the second title now prefixed to it.

The original work was justly deserving of the very great success which it achieved. It consisted of a corrected report of one of the well-known series of lectures to working-men delivered by the author in his capacity of Professor of Geology in the Royal School of Mines, at the Museum in Jermyn Street; and it was a model of clear exposition of a branch of science by one who was a master of his subject, and who at the same time had acquired great experience and skill in presenting it to popular audiences. Probably no better introduction to the principles of geology could possibly be recommended to the English reader than this little book of Prof. Ramsay's.

We must confess to feeling that this complete remodelling of the plan of a work that has already proved so successful, is a somewhat hazardous experiment. The original chapters of the book, which still retain the characteristics of popular lectures, do not always harmonise in style with the portions that were primarily intended for the pages of an encyclopædia. Indeed, as is admitted in the preface, the book now consists of two distinct works fused into one, and the reader is again and again reminded of the fact by somewhat awkward transitions and by abrupt changes in style and in the mode of treatment of the subject.

In almost every other respect we find the work to be worthy of the highest praise. The clearness and general accuracy of the information imparted by the book are as conspicuous in this as in the earlier editions, and Prof. Ramsay amply proves that he has not lost the most important gift which a teacher can possess, that of communicating his earnestness and enthusiasm to his readers. Many of the questions treated of at considerable length are of a somewhat controversial character, and the author has again and again to remark that he is teaching, not the universally accepted facts of the science, but the views which he himself has been led after long and careful study to adopt, and which he is sanguine enough to believe will be eventually accepted by all his brother geologists. Prof. Ramsay has certainly the merit of never being uncertain or hesitating in his convictions, and those who differ from, equally with those who coincide in opinion with him, will be glad to have the opportunity of reading his latest and most perfectly matured deliverances on questions in the discussions upon which he has long taken a very prominent part. We are bound to say that in respect to these matters he writes with the most perfect candour, and is ever ready to admit that there are subjects in which the timidity or caution of other geologists does not permit them to follow him in his bold generalisations.

The space at our disposal will not permit of our entering into detail on the numerous interesting questions suggested by a perusal of this book. The author's attempts to picture to the mind of his readers the ancient physical geography of our portion of the globe during successive geological periods may be cited as among the most graphic pieces of writing, and at the same time the most valuable portions of the work. Here Prof. Ramsay is evidently entirely in his element; he writes with an enthusiasm which is perfectly contagious, and his arguments, if not always sufficient to carry conviction, are at all times worthy of serious consideration.

We cannot resist quoting Prof. Ramsay's latest views on the important and much-vexed question of the classification of the Cambrian and Silurian rocks. On this subject he remarks:—

"If these strata were to be classified for the first time in England, with my present knowledge, I would divide them into three, as the most convenient method. The first series would include the purple and green grits and slates of the Longwynd and Wales, and range upwards as high as the top of the Tremadoc slates; the second would range from the base of the Arenig slates to the top of the Bala or Caradoc beds; and the third from the base of the Upper Llandovery beds to the top of the Ludlow rocks."

It is true that after this statement, which is in such perfect harmony with the results arrived at by palæontologists in Bohemia, Scandinavia, America, and our own country, Prof. Ramsay announces his intention of still adopting the nomenclature of Murchison and the Geological Survey, which he admits to be "old-fashioned;" but he states that his reason for doing so is simply that this plan will be the most convenient for those who wish to consult the geological maps and sections published by the Government. As the date fixed for the completion of the Government Survey is now passed, we may perhaps hope that the Director-General will be able to devote his attention to the much-needed reform of that old-fashioned classification and nomenclature. At all events, every geologist will be gratified by learning from so high an authority that any difference which may now exist concerning the classification of the older palæozoic rocks is mainly one as to the employment of certain terms, and that on the actual facts of the case something like substantial agreement has at last been arrived at.

On another question, that of the date of the earliest traces of human workmanship in this country, Prof. Ramsay's remarks are certainly not calculated to give quite so much satisfaction to his readers, He writes:—

"The antiquity of man being thus clearly established, it becomes obvious that his advent into our area was either of pre-glacial or of inter-glacial date. I say inter-glacial, because Mr. Skertchly has lately discovered palæolithic flint implements in certain brick-earths. Similar, and I believe identical, brick-earths underlie the 'chalky boulder-clay' in the neighbourhood, the boulder-clay having been removed by denudation from that

portion of the brick-earth in which the implements were found at Botany Bay, near Thetford, in Suffolk. The announcement at once provoked strenuous opposition, and therefore, on a tour of inspection of Mr. Skertchly's work with Mr. Bristow, we took care to examine into this point. The result was that I satisfied myself of the truth of Mr. Skertchly's observations that the implement bearing brick-earth in places underlies a boulder-clay, which, in his opinion, is not of the earliest date, in which case the men who made these tools must have been of inter-glacial age."

The "strenuous opposition" to which Prof. Ramsay refers, was directed, it will be remembered, not against the possibility of human remains being found under glacial deposits, but against such a conclusion being accepted without the clearest and most irrefragable evidence being adduced in its support. And it must be borne in mind that a number of most competent observers have examined the sections in question, and have arrived at conclusions directly opposed to those announced by the officers of the Geological Survey. When, therefore, our author, still speaking of this question of the contemporaneity of man with the glacial epoch, goes on to exclaim: "Perhaps we cannot prove it, but there is nothing improbable in the hypothesis, and I am not the only one who believes it," we cannot help entertaining the feeling that this is hardly the spirit in which a scientific question should be treated, and that the method which he adopts is one scarcely calculated to carry conviction to the mind of any competent judge of the matter.

In laying down this book we cannot refrain from once more expressing our opinion that it is a work of the highest value, and one worthy to take a foremost place among popular manuals of science. The illustrations are excellent; the woodcuts, by Mr. Sharman—giving a very faithful representation of species which have been selected by Mr. Etheridge as characteristic of the several formations—are quite new, and some views of scenery have also been added to those contained in former editions of the book. The little geological map of Great Britain, which we are glad to see reproduced, is a marvel of clear and accurate printing in colours, and well sustains the reputation of the publishing firm which has produced it.

FLORAL DIAGRAMS

Blüthendiagramme. Construirt und erläutert von Dr. A. W. Eichler, Professor der Botanik an der Universität Kiel. (Leipzig: W. Engelmann. Theil i., 1876, Theil ii., 1878.)

THIS book supplies a want that every real student of systematic botany must have felt. The introductory chapters are devoted to an inquiry into the morphology of the flower and its parts, and the inflorescence; while the subsequent chapters are a full exposition under the head of each family and order of the floral type and its most important modifications. Preceding each order is a list of the most important works bearing on it, and every quotation is accompanied by a full reference. Hence the book is both a Thesaurus of the literature of its subject, and moreover a Prodromus of phanerogamic morphology. Despite the modest title, the vegetative arrangements are explained wherever they present interest, and the same ungrudging pains are often extended to fruit and seed. Unlike too many authors Prof. Eichler is utterly free from provincialism. He cites as freely and constantly foreign botanists as those who have used the German language. Unfortunately we are but poorly represented, for morphological research is all but unknown in England, and is untaught by both our swarms of botanical lecturers and the great institutions which are the outward and visible sign of what Government recognises as botany. The medical curriculum has overborne original teaching by the former, the herbarium has stunted all else in the latter. Hence few of our botanists are able, like an Eichler or a Baillon, to check observations on the adult flower, with its parts distorted by drying and soaking, by their own knowledge of the growth of the living plant. Even the greatest sagacity and experience must be at a loss sometimes from this weakness in the very foundations of their work. For this reason one regrets the more that Eichler makes not a single reference to the works of Griffith, perhaps the greatest botanical genius England ever possessed, who found out for himself the value of developmental research and worked out many a flower by its aid.

A word on the method of Eichler. The actual editor of the "Flora Braziliensis," he adds to his thorough knowledge of morphology proper a rare acquaintance with systematic botany. Hence he belongs to no school, though awake to the value of workers in more limited fields, in all of which he himself has done good service. A firm evolutionist, he accepts the testimony of systematist, anatomist, teratologist, organogenist, and histogenist, and believes that all of these can in turn shed light on doubtful points. Hence his opinion must be respectfully considered by those who differ from it, and it is worth while to note a few of his conclusions.

He regards the nature of the "calyx tube" as varying with the order; truly receptacular in Rosaceæ, for instance, it is, partly at least, appendicular in some cases. The petals of Primulaceæ are regarded as true petals, and not as appendages of the stamens, a view which our descendants will have forgotten or unearth with the lazy amusement with which we look on some of the naif theories of our ancestors. The nature of the placenta and ovule is a more difficult question, and our author, who, in the preliminary chapters of Part i., published in 1876, held it essentially variable, has been led chiefly by Celanowsky's arguments to regard it as in all cases an outgrowth from the carpellary leaves. Similarly, the ovule, regarded in the First Part as a bud, is now viewed as an emergence. Of course the last word is not yet said on these points, but it is worth noting that Warming also avows his final conversion by Celakowsky, in his brilliant paper on the ovule in the first volume of the *Annales des Sciences Naturelles* for 1877; and Eichler is at one with Warming in adopting Brown's view of the female flower of Gymnosperms. It is much to be regretted that this point was not really discussed at the late congress in Paris, or that its principal advocates do not answer the latest arguments in its favour. But the question cannot at all be regarded as settled.

The cup of *Euphorbia* is regarded as an inflorescence; but though the *pros* and *cons* are fairly stated, no new light is shed on the matter.

Enough has been said to show the extreme value of the book to the scientific botanist. May its teachings quicken sound study in England. MARCUS M. HARTOG

OUR BOOK SHELF

Manuel du Voyageur. Par D. Kaltbrunner, Membre de la Société de Géographie de Genève. (Zurich, J. Wurster und Cie, Editeurs. Paris, C. Rheinwald und Cie, 1879.)

A GREAT difficulty of writing a treatise for the use of travellers, on "What to Observe," lies in the impossibility of presenting to the imagination an ideal average traveller to address. If the great mass of intending travellers had much the same amount of scientific knowledge and were well grounded in the elements of science generally, a very useful and compact work might, no doubt, be composed. But as a matter of fact such persons are usually very ignorant, or variously ignorant, and a book fitted to instruct the whole of them must omit none of the more elementary considerations, and therefore would assume the shape of a collection of encyclopædic treatises. It is hard to define the level of previous knowledge to which "Kaltbrunner's Manuel du Voyageur" is best adapted. Every reader is sure to think it too diffuse for his own wants in some parts, neither deep nor full enough in a great many, and probably beyond his depth in others; but take it all in all, it is perhaps better adapted for persons of moderate culture than any similar book that could be named. It is beautifully got up, with abundant illustrations, and to say the least, would be often useful for reference and as a reminder. The range of its topics is wide enough to touch the interests of everybody, and it would be a capital present to give to a friend bound for foreign parts. Considerable space is allotted to subjects connected with social life and other anthropological questions.

There seems to be some irony in the fact that when the world is so nearly explored, manuals for the use of travellers should begin to appear. They were greatly needed many years ago, when the Admiralty Manual had the field nearly all to itself, but now that the need is less, these works are at last composed in abundance. The present one, however, is by no means intended to supply the wants of those travellers only who are exploring unknown countries, much of it being applicable even to home districts. It is less solid and more comprehensive than the recent German publication, "Anleitung, &c.," by Neumayer.

Pleasant Ways in Science. By R. A. Proctor. (London: Chatto and Windus, 1879.)

OF this book, which has been sent me for review, I can truly say that it is an excellent specimen of what has been well called (I forget by whom) *Paper Science.* A very few quotations will amply justify this verdict.

At pp. 8, 152, I find "heat" several times standing for "temperature." But the author (in these columns, vol. xvi. p. 227) insisted that

"What *mathematicians call* the *moving force* exerted by the earth on the moon is eighty-one times greater than the corresponding force exerted by the moon on the earth."

To put "heat" for "temperature" is after all not very strange for one who puts "moving force" for "accelerating force."

In the account given of the experiments of Andrews and Tait on ozone, the action of "iodine" is given as that of "mercury": and the now-received idea of the nature of ozone—though *twice* mentioned in the paper referred to—is described as a "beautiful" and "ingeniously conceived" hypothesis suggested after the publication of the paper (pp. 351-2). . . .

The following passage, which refers to friends of my own, I quote without comment:—

". . . . no one, I think, would believe so ill of his fellow-men as to suppose for one moment that *advantage could be taken of the sympathies which have been aroused by the Indian famine*, or which may from time to time be excited by the record of great disasters by sea and land, *to advocate bottomless schemes merely for purposes of personal advancement.* We must now, *perforce*, believe that those who advocate the erection of new observatories and laboratories for studying the physics of the sun have the most thorough faith in the scheme which they proffer . . . ." (p. 51).

From p. 194 I gather that I know nothing about the motion of waves, and p. 240 proves me equally ignorant of voltaic electricity. I cannot read any more.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Receiving Telephones

I HAVE roughly tried two experiments which seemed likely to supply new forms of receiving telephones, and have had such partial success as seemed satisfactory in preliminary trials. As I have not time to continue the experiments I request the insertion of this note in the pages of NATURE, in the hope that some one else will follow the matter up.

In one experiment a spiral wire (I used German silver, but it may be of any material) was wound closely so that the spires were in contact, or nearly so. One end of the spiral was fixed and the other end attached by a thread to the middle of a small parchment drum-head, such as is sold by the toy-makers for thread telephones. A slight tension was put on the thread to draw the spires of wire slightly asunder. The spiral wire was then made part of a circuit, including one or two cells of Grove's battery and a line wire going to another room. By this apparatus such sounds as the scraping on a file were satisfactorily heard, although the spiral was only one coil of about an inch long. It will be observed that in this arrangement there are no magnets; the whole effect is produced by the varying induction of the current upon itself. The apparatus could obviously be rendered more efficient by using a longer spiral, or a coil consisting of a number of concentric spirals not quite in contact, so as to allow small motions to exist. The induction might be still farther increased by using a spiral of two wires, so that a powerful local current might be kept up in the alternate spires, while the varying line-current is passing through the intermediate ones. Another improvement would consist in using iron wire wound in a sufficiently loose coil. The self-magnetisation of this coil would co-operate with the electric induction to heighten the effect.

In the other arrangement an iron or steel spiral (in my experiment it was an ordinary steel spiral spring, of which the spires lay close) was placed inside a coil of copper wire in circuit with a battery and the line. The spiral, as before, was fixed at one end, and kept slightly stretched by a string connecting its other end to a drum-head. In this arrangement no current passes through the spiral, but it is the core of an electro-magnet, and becomes magnetised in a degree which changes with the alterations in the intensity of the line-current. This causes the spires to attract one another with varying intensity, and the tremulous motion so produced is propagated by the string to the parchment. By this arrangement singing, whistling, &c., were heard when a Reiss transmitter was used. Probably a soft iron coil would have been better than the steel spring I used, and the apparatus is susceptible of other obvious improvements which would add to its sensitiveness.

Before concluding permit me to thank Prof. Barrett for allowing me to make the experiments in his laboratory.

Dublin, November 25 G. JOHNSTONE STONEY

The Microphone for Military and Tonometric Purposes

MY attention has just been called to a paper on the microphone, by Prof. W. F. Barrett, in NATURE (vol. xix. p. 12), in which it is asked whether the latter "has ever been tried by military men to detect the mining operations of an enemy?" Will you allow me to state that this application of the microphone suggested itself to me many months ago, and that I have begun to make experiments both in this direction and also with a view to ascertain to what extent sounds can be transmitted to a microphone immersed in water. Unfortunately the pressure of other matters has hindered me from completing the work, which, however, I hope shortly to be able to do.

May I take this opportunity of saying that I have been endeavouring with some success to apply the principle of the microphone to the counting of the beats of two slightly dissonant tuning-forks. In one experiment the two forks were inverted and screwed through a board above which the ends of their stems protruded. A thin piece of carbon was laid over these ends and the arrangement was placed in circuit with a Bell telephone. The beats were loudly heard and continued audible long after their direct sound had ceased. A reflecting galvanometer being placed in the circuit the beats were shown by deflections of the light spot, but irregularities in the current made it difficult to count them satisfactorily. The forks were then screwed horizontally into a vertical board and a screw was inserted about 1" from the stem of each and on the same horizontal level. A small piece of carbon was laid over each stem and its adjacent screw. This plan gave even better results, and admits of the forks being any reasonable distance apart. The experiments were tried with two forks whose vibration numbers were about 60, and also with a pair of octave forks with vibration numbers of about 256 and 512. A small piece of copper wire was then attached to each of the two large forks, and mercury cups were so placed that the points of the wires were just not touching the mercury surface when the forks were at rest. Both mercury cups were connected to one pole of the battery, and the current was arranged to branch through the forks uniting at the telephone. The beats were very loud. This plan, however, involves difficulties on account of the delicacy of adjustment required for the mercury surfaces and also the amalgamation of the copper-points. Several other experiments have been tried, but the method first described seems worth a trial by those interested in tonometry. The counting of beats, which is not an easy matter for aged or unaccustomed ears, may thus be immensely facilitated, while the period of the forks under observation is absolutely unaffected. The carbon used was that employed for the electric light, and it is probable that more carefully prepared and homogeneous material would have given better results in a galvanometer experiment.

Cooper's Hill, November 19

The Microphone as a Receiver

ON the 3rd of June last, in a paper read before the Royal Society of Edinburgh, I described an experiment which showed that the microphone could be used, not only as a transmitter, but also as a receiver of articulate sounds. An abstract of the paper appeared shortly after in NATURE, and since then I have had communications from several experimenters, stating that they had failed to repeat the experiment, and asking for some details regarding it. I trust, therefore, that you will kindly give me space for a short explanation.

In performing the experiment the transmitting and receiving instruments which I used were precisely identical. Each was merely an ordinary white porcelain jam-pot, $3\frac{1}{2}$ inches in diameter and 4 inches deep, half filled with gas-coke, broken into coarse fragments and provided with electrodes whereby a current of electricity could be sent through the pieces of coke. Cinders from ordinary coal, if well burned, would, of course, do equally well. The electrodes were two strips of tin about two inches wide slipped down, opposite to each other, between the cinders and the sides of the jam-pot and fastened by being bent over the edges and bound round the outside with a cord. When these jam-pots were put in circuit like a pair of ordinary telephones, and a battery of two strong Grove's cells, or four ordinary Bunsen's, included in the circuit the arrangement was complete.

In this way I have had no difficulty in making myself and others clearly hear the transmission both of singing and speaking, although, as I stated in my paper, the articulation is not so distinct as I have no doubt it will be when proper forms both of transmitter and receiver are adopted.

I may mention that since then I have found the result to be greatly improved by including a stronger battery in the circuit.

Edinburgh, November 18

JAMES BLYTH

Wind-Pressure

I BECAME acquainted, some years since, with the singularly great wind-pressures registered at the Liverpool Observatory, and I should be rather disposed to attribute them to the exceptional position of the wind-gauge than to think (as the writer of an article in NATURE, vol. xix. p. 25, appears to do) that the gauge is erroneous. I do not remember to have seen it noticed, in the recent discussions on the Cleopatra's Needle, that there is probably a rapid increase of wind-pressure from the ground-surface upwards. In any river the velocity is least at the bottom, and near the bottom the change is rapid. Similarly, in the great current formed by the wind, I imagine there is a much less velocity near the ground than at some distance above it, and less on a plain than above a hill standing out of the plain. Now I believe the Bidstone Observatory is on a hill, with the great plain formed by the Atlantic in front of it. It is, therefore, in a position in which it receives an exceptionally heavy wind-pressure. The pressure on the wind-gauge is probably much greater than on the windows of the observatory, and that, again, is probably greater than the pressure on buildings more inland, where the current near the ground has been more interfered with by obstructions. On the other hand, Cleopatra's Needle is in a very protected position, where I should be much surprised to find that the wind-pressure ever reached even 40 lbs. per square foot.

As Mr. Dixon has referred to the case of a window to disprove the possibility of a pressure of 80 lbs. per square foot, it may be well to see whether it is really conclusive. I have not at hand any formula for the resistance of a simply-supported square plate, but it will not be very different from that of a circular plate. Now, let p = pressure per square inch on surface of plate, t its thickness, r its radius. Then the greatest stress in the plate is by Grashof's formula, $f = \frac{5}{6} \cdot \frac{r^2}{t^2} p$. Taking a plate of glass 2 feet diameter, $\frac{1}{8}$ inch thick, and loaded with 80 lbs. per square foot, we get $f = 4{,}270$ lbs. per square inch. In some experiments which I made under Sir W. Fairbairn's direction, the tenacity of glass was found to be from 4,200 to 6,000 lbs. per square in. Hence, surprising as it may seem, it is probable that a pane of glass 2 feet diameter would sustain a load of 80 lbs. per square foot, uniformly distributed, without breaking, or a load equivalent to that of a dense crowd of people. I don't, of course, think that a window would be safe if subjected to such a pressure, but it is always desirable to subject general statements of this kind to exact calculation; and I think we may at least infer that well-constructed glass windows would sustain a considerable wind-pressure without necessarily giving way.

Cooper's Hill, November 17

Was Homer Colour-blind?

I CRAVE some little space for a few remarks with regard to the recently much vexed question as to the traditional blindness of Homer.

It seems to have been overlooked that, apart from the statement made by Herodotus[1] (in his life of Homer), that in

[1] Homer, according to Herodotus, was born about 167 years after the Trojan war and, when still a child, adopted by his stepfather, to whom he succeeded in the management of a school. At an early age, however, it would seem, he set out for distant voyages and, at length, after having spent some time on visiting Tyrrhenia and Iberia, when about 32 or 34 years of age, lost his sight from what appears to have been some chronic disease of the eyes. Previously, when at Ithaca, he is said already to have had a narrow escape from that calamity. The text of this important narrative runs thus:—

. . . . *οἱ μὲν Ἰθακήσιοι λέγουσι, τότε μὲν παρ᾽ ἑαυτοῖς τυφλωθῆναι, ὡς δὲ ἐγώ φήμι τότε μὲν ὑγιῆ γενέσθαι, ὕστερον δὲ ἐν Κολοφῶνι τυφλωθῆναι; συνομολογοῦσι δὲ μοι καὶ Κολοφώνιοι τούτοις . . . . . . Ἀπικομένῳ δὲ ἐς Κολοφῶνα συνέβη, πάλιν νοσήσαντα τοὺς ὀφθαλμοὺς μὴ δύνασθαι διαφυγεῖν τὴν νόσον, ἀλλὰ τυφλωθῆναι ἐνταῦθα. Ἐκ δὲ τῆς Κολοφῶνος τυφλὸς ἐὼν ἀπικνέεται εἰς τὴν Σμύρναν* . . . .

From Colophon he sailed to Smyrna, where, for his sustenance, he began and, afterwards, continued, during his long wanderings, and for a good many years, the recital of his verses.

consequence of what appears to have been a chronic disease of the eyes, the poet lost his sight at the early age of about 32 or 34 years, and that he, once at least, styles himself a downright blind man, in his Hymn to Delian Apollo, ver. 169—73, which derives no mean authenticity from being so pointedly quoted by Thucydides, III., 104, and which runs thus:—

> . . . . *ὁππότε κέν τις ἐπιχθονίων ἀνθρώπων*
> *ἐνθάδ' ἀνείρηται ξεῖνιος ταλαπείριος ἐλθών·*
> *ὠ κοῦραι, τίς δ' ὔμμιν ἀνὴρ ἥδιστος ἀοιδῶν*
> *ἐνθ'δε πωλεῖται, καὶ τέῳ τέρπεσθε μάλιστα;*
> *ὑμεῖς δ' εὖ μάλα πᾶσαι ὑποκρίνασθ' εὐφήμως·*
> *τυφλὸς ἀνὴρ, οἰκεῖ δὲ Χίῳ ἔνι παιπαλοέσσῃ,*
> *τοῦ πᾶσαι μετόπισθεν ἀριστεύουσιν ἀοιδαί.*

> If some day an earthborn man, a wayfaring stranger,
> Asks you the name of whom best you like of all the minstrels you know,
> Whose songs are, oh lasses, the most delightful to you,
> Oh, then, unanimously, surely, you answer:
> It is the blind man who dwells in the rocky island of Chios,
> His songs are to us by far the sweetest of all.

I need not add, as a further argument, that Homer frequently was alluded to as the blind and humpbacked man, *ὁ κυφὸς καὶ τυφλὸς ἀνήρ*,[1] and it seems to me trifling to qualify, or mitigate, the racy juxtaposition of the two epithets.

To what extent colour hallucinations, so frequent in connection with certain forms of blindness, may possibly have impaired the poet's imaginative faculties with regard to the varying hues and shades of colour, it would be for the present, from want, for obvious reasons, of similar observations, difficult to settle. However, I cannot but think that what by some so recently has been called Homer's colour-blindness may be the natural consequence, on the one hand, of the increasing dimness of his recollections as well as owing to these optical hallucinations, and finally, to the defective chromatic terminology of his time. The following are some of the Greek and Latin authors who, together with Herodotus, aver and enlarge upon the blindness of Homer:—Plutarch, Vita Hom. 12; Thucyd., III. 104; Pausan., II. 33, 3; III. 4, 33; Lycophron, Cassandra, 422; Aristot., Orat., L. p. 703; Cicero, Tuscul, V. 39.

I refrain from discussing the question whether, from a physiological point of view, such a profound functional perturbation as is involved in the term of colour-blindness, viz., deficiency in the perception of any plurality of colours in the spectrum, would not seem to be symptomatical of most momentous organic disturbances in the nervous apparatus of the eye, generally conducive to the most hopeless forms of blindness.

Scientific Club J. HERSCHEL

IN reading Mr. Pole's article on Homer's sensations of colour, there is one point which seemed to me to call for explanation. Mr. Pole says that in the solar spectrum he sees only two colours, blue and yellow, and that the red space appears to him yellow. From this one would naturally infer that the whole of the spectrum visible to ordinary persons is visible to him also, but that it presents only these two colours, which graduate into one another without any break, and that the green space appears as yellow. And with a colour-blind person who has allowed me to test his capabilities, I found this actually to be the case. But later on Mr. Pole says that pure red and pure green appear to him not yellow but grey. I would wish, then, to ask Mr. Pole whether the spectrum presents to his vision, in place of the green, a neutral space or an interval of darkness? In other words, have the rays of that particular refrangibility no action at all upon his retina, or is it that they have no action peculiar to themselves, but simply produce the general effect of light? In either case the phenomenon seems more anomalous than if he saw all colours as colours, though he could only class them under two heads. To take a familiar analogy, it is as if a man should be perfectly able to distinguish the pitch of notes at either end of the scale, but the notes between should either not affect the auditory nerve at all, or should affect it simply as noise.

Pembroke College, Oxford FRANK PODMORE

Anthropometry

As I have stated in the preface that my object in publishing my "Manual of Anthropometry" is to invite criticism with a view to perfecting the anthropometrical chart which it contains, and which forms its chief feature, I may be excused for referring to the notice of the work which appears in NATURE, vol. xix. p. 29. The reviewer objects to the large number of measurements given in the chart, but he has overlooked my statement that many of them are of a secondary character, and that I leave the student liberty to select the measurements which best suit his purpose, requiring only of him that they shall be made and recorded in a uniform manner, and thus become the common property of statisticians. Anthropometry can make no progress as a science, so long as observers are at liberty to make the same nominal measurement of the body in four or five different ways, as is the case, for instance, with chest-girths.

I may add that my manual was not written for the three or four individuals in this country who have mastered the "theory of human proportions" as a mathematical curiosity, but for army surgeons, busy medical men, schoolmasters, and others who are much more concerned with actual facts than theories of probabilities. CHARLES ROBERTS

Bolton Row, W.

Divisibility of Electric Light

IN all communications on this subject in NATURE and elsewhere, the division of light is considered only with reference to parallel circuits, and this naturally causes great loss of light by the law that heating is proportional to the square of the current. But in electric circuits their resistance has always to be considered; and if two lamps are taken parallel, only half the resistance of the one lamp is obtained, and such resistance can be obtained by taking two parallel circuits of two lamps in series in each; the light obtained then is one quarter in each lamp, as half the current is flowing through each circuit, and as four quarters make a whole, no loss of light is caused by division in such a method of one current to any number of lamps. There are certainly practical difficulties in the way of burning lamps in series, though these are greatly diminished if incandescent wire is used as the light-emitting source. However, there is no inherent reason why the electric light should be wasteful in division, as is described by Mr. Trant. F. JACOB

Verification of Pervouchine's Statements regarding the Divisibility of Certain Numbers

THE statements of Pervouchine, reported in some recent numbers of NATURE, are equivalent to the following:—That the 2^{10} power of 16 is less by 1 than some multiple of $7 \times 2^{14} + 1$; and the 2^{21} power of 16 is less by 1 than some multiple of $5 \times 2^{25} + 1$.

Let r_n be the remainder after dividing the 2^n power of 16 by one of the above divisors. Then since the 2^{n+1} power of 16 is the square of the 2^n power, r_{n+1} differs from the square of r_n by a multiple of the divisor; or r_{n+1} is the remainder arising from the division of the square of r_n.

Use for the work the scale whose radix is 16. In this scale the above divisors are

1 12 0 0 1 and 10 0 0 0 0 0 1.

In the first case, calculating on the plan indicated, we find the remainders.

r_3 = –		5	2	4	9
r_4 = –	1	11	6	4	13
r_5 = –		5	9	10	6
r_6 = –		15	10	4	13
r_7 = –		1	0	10	15
r_8 = –	1	10	8	15	15
r_9 = –		14	5	2	11
r_{10} = –					1

[1] The very word of Ὅμηρος signified "blind" in the vernacular idiom of Κύμη, or Cumæ, one of the Æolian colonies in Asia Minor, where he lived for some time, and, as will be shown anon, accidentally came by the name of Homer, his original name being Melesigenes, from his happening to be born on the banks of the small river Meles, which flows by Smyrna and runs into the Smyrnæan sinus.

One day, pointing out how much of the poet's glory was certain to redound to their own city's glory, if the poet could be induced to settle among them, it was proposed to the people of Cumæ to provide during his lifetime for his wants, at the public expense, when somebody explained that such a resolution would be tantamount to inviting all sorts of blind, Ὅμηροι, and useless, people to their city, whereupon the proposal dropped. But it seems that, henceforth, the poet went by the name of Homer:—

Ὅμηρος ἐπεκράτησε τῷ Μελησιγενεῖ ἀπὸ τῆς συμφορῆς; οἱ γὰρ Κυμαῖοι τοὺς τυφλοὺς Ὁμήρους λέγουσιν. Ὥστε πρότερον ὀνομαζομένου αὐτοῦ Μελησιγενέος, τοῦτο γενέσθαι τοὔνομα Ὅμηρος.

Herodot. Halic., vita Hom., 2, 13.

Consequently the 2^{10} power of 16, or the 2^{12} power of 2, increased by 1, is divisible by $7 \times 2^{14} + 1$

In the second case, we find the remainders

$r_3 =$	− 4	0	0	0	0	1	10
$r_4 =$	− 7	9	9	9	7	0	11
$r_5 =$	− 9	8	2	10	9	9	4
$r_6 =$	− 4	6	6	11	8	8	11
$r_7 =$	− 2	2	3	12	10	8	5
$r_8 =$	− 9	14	1	0	14	6	10
$r_9 =$	− 6	9	14	11	8	11	0
$r_{10} =$	− 3	14	4	6	15	1	3
$r_{11} =$	− 7	7	10	5	12	10	4
$r_{12} =$	− 7	12	1	4	5	1	4
$r_{13} =$	− 7	3	7	12	8	1	2
$r_{14} =$	− 5	1	13	9	4	6	4
$r_{15} =$	− 3	15	2	2	4	13	3
$r_{16} =$	− 1	5	6	9	1	2	6
$r_{17} =$	− 2	5	9	12	5	9	3
$r_{18} =$	− 7	13	11	14	2	8	5
$r_{19} =$	− 8	3	0	0	6	15	7
$r_{20} =$	− 3	14	3	10	2	11	0
$r_{21} =$	−						1

Consequently, the 2^{21} power of 16, or the 2^{23} power of 2, increased by 1, is divisible by $5 \times 2^{25} + 1$.

The work involved in the first verification can be done by a good calculator in less than half-an-hour; the second is, I think, not more than thrice as long, for the divisions are more easily performed.

Here is one of the eighteen stages of the work of the second verification, namely, the getting of r_6 from r_5.

```
r5 = 9  8  2 10  9  9  4
   ---------------------
     9                         5  1
  1  2  8                         9  4  0
  1  3  0  2                         2  6  0  4
  1  3  0  4 10                         11 14  2 14  4
  1  3  0  5  4  9                         10 11  2 15  9  1
  1  3  0  5  5  2  9                         10 11  2 15 14  7  1
  1  3  0  5  5  3  2  4                          4 12  1  5  4 12  9  0
                               ---------------------------------------------
                               5 10  7  2  9 13  1  2
                               5  0  7  4  3  1  7, 4 10  4 11 13  0  0 +
                                                    9  0 11  7  6  1 11 −
                                                    -----------------------
                                            r6 = −  4  6  6 11  8  8 11
```

The last four lines of the work are made up thus:—In adding the parts of the square depress the last six places to line 2, leaving the rest in line 1; then proceeding to the extreme left, carry the tens figure, in this case 0, six places to the right, for subtraction into line 3, and depress the units figure (5) into line 2. Multiply the just depressed figure (5) by 16, and add to it what is found (10) in the place to the right of it in line 1 (giving 90); again carry the tens figure (9) for subtraction into line 3, and depress the units figure into line 2; repeat the process, moving to the right, until line 1 is exhausted; then the difference between line 3 and the last seven places of line 2 gives line 4, the result required.

For the sake of safety, before proceeding to calculate r_7, calculate r_6 again from the complement of r_6 with reference to the divisor, in this case from + 7 13 5 6 6 13. If the same result is again obtained, you may go on confidently.

Hampstead JOHN BRIDGE

Vulcan and Bode's Law

IN the year 1778—just a hundred years ago—the astronomer Bode published an approximation to a law respecting the planetary distances. He took the numbers

0, 3, 6, 12, 24, 48, 96, 192, 384,

each after the second being double the preceding; to these he added 4, giving

4, 7, 10, 16, 28, 52, 100, 196, 388,

numbers which, with the exception of the last, agree very well with the distances of the planets from the sun:—

3·8, 7·2, 10, 15·2, (27), 52, 95·3, 191·8, 300·3.

The publication of this law, at a time when the asteroids between Mars and Jupiter were as yet undiscovered, drew attention to Kepler's speculation that a planet was wanting between Mars and Jupiter. Twenty-one years after Ceres, the first of the asteroids, was discovered, and then others, until now there are nearly 200, the average distance of the whole being 27, and agreeing very well with Bode's number 28. All this is doubtless known to the majority of your readers.

In calling attention to the law, while not wishing to attach too much importance to it, I would point out one or two suggestions which present themselves. If we place 3 before the 0 in the first row of figures the line becomes

− 3, 0, 3, 6, 12, &c.

If 4 be now added the numbers are

1, 4, 7, 10, 16, &c.

The number 4 in this line represents the relative distance of Mercury from the sun; may not the number 1 represent the distance of Vulcan, or more probably the mean distance of a ring of asteroids, of which Vulcan is the brightest?

Referring now to the modified law, represented by the numbers

1, 4, 7, 10, 16, 28, 52, 100, 196, 388,

if 1 represents the mean distance of the Vulcan-asteroids, and 28 that of the Ceres-asteroids, it is a fact that after the first ring come four planets, Mercury, Venus, Earth, Mars, and after the second ring four planets, Jupiter, Saturn, Uranus, Neptune, the two sets of planets having marked differences as regards axial rotation and density.

What, then, is beyond Neptune? The law seems to say, a ring of asteroids at an average distance of 772. The motion of Neptune does not lead astronomers to suspect a planet beyond. Perhaps the optical instruments of the future may help to answer this question, Is there a ring of asteroids beyond Neptune? B. G. JENKINS

Irish Bog Oak

CAN you or any correspondent kindly give me the scientific name of the Irish "bog-oak" (fossil)? It should be either *Quercus pedunculata* or *Q. sessiliflora*, the existing species, but though I have seen many specimens, I never got hold of one which would enable me to determine the species, and, for aught I know, there may be some of both. W. F. SINCLAIR

46, Guilford Street, W.C.

OUR ASTRONOMICAL COLUMN

THE TOTAL SOLAR ECLIPSE OF JANUARY 11, 1880.—The central line in this eclipse ends soon after reaching the coast of California, where it is possible totality may be witnessed close upon sunset. Tracing the previous path of the shadow through its long course across the Pacific with the aid of the Admiralty chart, it will be found that the only islands included within it are the Coquille, Bonham, and Elizabeth Islands, lying near together, between 169° and 170° E. longitude, and belonging to the Marshall Islands group. The eclipse passes centrally over the largest of the Coquilles, as laid down in the Admiralty chart of this group, according to a calculation in which the moon's place has been made to accord very nearly with Hansen corrected to Newcomb, which gives the following track:—

Long. E.	Lat. N. limit.	Lat. Cent. line.	Lat. S. limit.
°	° ′	° ′	° ′
168	... + 6 44·6	... + 6 28·0	... + 6 11·6
170	... 6 20·3	... 6 3·8	... 5 47·3
172	... 5 57·8	... 5 41·4	... 5 24·8

So that the breadth of the shadow in the direction of the meridian does not exceed 33′. Reading off from the chart, it will be found that the centre of the largest of the Coquille Islands is in about 169° 35′·5 E. and 6° 8′·5 N., and, calculating directly for this point, it appears that the total eclipse will commence at 8h. 41m. 25s. A.M. on January 12, local mean time, and continue 1m. 16s., and this represents the most favourable condition under which the eclipse can be observed on land. For any other point within the shadow in this vicinity the duration of totality may be determined by the fol-

lowing formulæ, where L is the east longitude from Greenwich, l the geocentric latitude, and t the Greenwich mean time of beginning or ending, according as the upper or lower sign is employed :—

$$\text{Cos. } w = +\ 109{\cdot}0051 - [2{\cdot}34285] \sin. l + [1{\cdot}98006] \cos. l \cos. (L - 15^\circ\ 15'{\cdot}9).$$
$$t = 11\text{h. } 10\text{m. } 48{\cdot}9\text{s.} \mp [1{\cdot}58154] \sin. w + [3{\cdot}16228] \sin. l.$$
$$- [3{\cdot}95668] \cos. l. \cos. (L - 126^\circ\ 35'{\cdot}7).$$

TRANSITS OF MERCURY.—Prof. Holden has published an "Index-Catalogue of Books and Memoirs on the Transits of Mercury," which he had prepared to aid him in a search for records of the physical phenomena which have been observed at such transits. The list is not quite a complete one, the publications of observatories not being included, but there is little inconvenience in the omission, as such observations and memoirs can be found by reference to the volumes for transit years, and Prof. Holden gives a list of the dates of all the transits of Mercury so far observed. Catalogues of this description must prove most serviceable to the student and to every one who has occasion to consult the general literature of an astronomical subject, and we hope the American astronomer may find leisure to continue them. Reference has already been made in this column to his very valuable "Index-Catalogue to the Literature of Nebulæ and Clusters," &c., forming No. 311 of the "Smithsonian Miscellaneous Collections." The publication above mentioned forms No. 1 of "Biographical Contributions," edited by Justin Winsor, Librarian of Harvard University. The copy before us is republished from the *Bulletin* of the library for October, 1878.

BIELA'S COMET AND JUPITER IN 1794.—It will be remembered by those who may have interested themselves in cometary astronomy, that between the first appearance of Biela's comet in 1772, and the next return at which it was observed, in the latter part of 1805, the elements had undergone alterations of a magnitude that occasioned doubts as to the identity of the comets, notwithstanding the general similarity of orbits, Bessel pronouncing against it, while Gauss pointed out that more than one revolution must have been accomplished in the interval, so as to admit of the comet having approached one of the larger planets and thereby experienced perturbation to account for the differences in several of the elements. The disturbing body is now known to have been the planet Jupiter, and there has been no difficulty in fixing the epoch when the comet's motion was most deflected, but we do not recollect to have seen the particulars of the near approach of the two bodies stated in any astronomical work. Starting from the final elements for perihelion passage in 1806, determined in the masterly investigation of the late Prof. Hubbard of Washington, it appears that neglecting planetary perturbation in the interval, the comet would have made its nearest approach to the planet at the beginning of June, 1794, when their distance was less than 0·47 of the mean distance of the earth from the sun. The following distances have been similarly obtained :—

1794	Distance from Jupiter.	1794	Distance from Jupiter.
March 2	0·654	May 31	0·469
April 1	0·562	June 15	0·473
May 1	0·496	,, 30	0·488
,, 16	0·477		

At the time of closest approximation, the heliocentric longitude of the comet was about 269° 40′, and the latitude + 4° 25′.

BIOLOGICAL NOTES

GALL-MAKING INSECTS.—At the St. Louis meeting of the American Association Prof. C. V. Riley read a paper on the gall-making *Pemphiginæ*. He said that the life-history and agamic multiplication of the plant-lice (*Aphididæ*) have always excited the interest of entomologists as well as of anatomists and embryologists. The life-history, however, of the gall-making species belonging to the *Pemphiginæ* has baffled the skill of observers more than that of any other group. Mr. Riley is about to publish some new biological discoveries relating to this family of insects, in connection with a descriptive and monographic paper by Mr. J. Monell, of the St. Louis Botanic Gardens. The paper laid before the Association simply records some of the yet unpublished facts discovered. All of the older writers, in treating of the different gall-producing *Pemphiginæ* of Europe, have invariably failed to trace the life-history of the different species after the winged females leave the galls, and, with few exceptions, have erroneously inferred that the direct issue from the winged females hibernates somewhere. The most recent production on the subject is a paper published in the present year in Cassel, by Dr. H. F. Kessler, which is entitled the "Life-History of the Gall-Making Plant-Lice, affecting *Ulmus campestris*." The author, by a series of ingenious experiments, rightly came to the conclusion that the insects hibernate on the trunk, but he failed to discover in what condition they so hibernate. Led by his previous investigations into the habits of the grape Phylloxera, Mr. Riley discovered, in 1872, that some of our elm-feeding species of *Pemphiginæ* produce wingless and mouthless males and females, and that the female lays but one solitary impregnated egg. Continuing his observations, especially during the present summer, he has been able to trace the life-history of those species producing galls on our own elms, and to show that they all agree in this respect, and that the impregnated egg produced by the female is consigned to the sheltered portions of the trunk of the tree and there hibernates—the issue therefrom being the stem-mother which founds the gall-inhabiting colony the ensuing spring. Thus the analogy in the life-history of the *Pemphiginæ* and the *Phylloxerinæ* is established, and the question as to what becomes of the winged insects after they leave the galls is no longer an open one. They instinctively seek the bark of the tree and there give birth to the sexual individuals, either directly or (in one species) through intervening generations.

LEAF ABSORPTION IN PLANTS.—The earlier experimenters on this subject, M. Perault, to wit, and Hales (1731), were persuaded that leaves absorbed dew and rain. For over a century the investigations of others supported this view, until M. Duchartre, in 1857, from his experiments, advanced a contrary opinion—that now held by most vegetable physiologists, and commonly taught in our schools. But, strange to say, gardeners, in their every-day operations, adopt a different notion from that prevailing in science. The subject has recently received the attention of the Rev. G. Henslow, who, in a paper read before the Linnean Society (November 7), shows that, while it may be true that, as Duchartre has said, dew is not absorbed by saturated tissues at night; yet, on the contrary, his (Henslow's) experiments go to prove that absorption *does take place* at and after sunrise, when transpiration recommences, and an indraught is caused by the moisture, wherever lingering on the leaves. He further corroborates M. Boussingault's late assertion, that, when leaves are purposely or naturally killed by excessive drought, they then do absorb water, as proved by the balance, or otherwise.

BRITISH NEWTS.—From an article by M. Ferrand Lataste in the last volume of the *Journal* of the Société Zoologique de France, it appears that the supposed fourth species of British newt—Gray's banded newt (*Ommatotriton vittatus*) of Mr. Cooke's "Our Reptiles"—may be altogether removed from the British catalogue. It was first introduced into the British list by Jenyns, in 1835, on the faith of some specimens found in a bottle in the

British Museum by the late Dr. Gray, which, being associated with some British newts, were supposed to have been obtained in the neighbourhood of London. Through a somewhat similar error, some specimens in the collection of the Jardin des Plantes at Paris were believed by Valenciennes to have been obtained in France, near Toul, and other examples were supposed to have been found living at Antwerp. It has thus come to pass that naturalists, copying one from another, have assigned "England, France, and Belgium" as the locality of this newt. It now turns out, from M. Lataste's researches, that all these localities are erroneous, and that the so-called *Triton vittatus* is no other than the *Triton ophryticus* of Berthold, an Eastern species of newt which is found in Syria and Asia Minor. The British newts are now, therefore, reduced to three in number—the crested newt (*Triton cristatus*) and the smooth newt (*Triton tæniatus*), both of ordinary occurrence, and the rarer palmated newt (*T. palmatus*).

SPERM WHALES ON EUROPEAN COASTS.—Prof. Turner, of Edinburgh, has been collecting and investigating a number of rare prints of sperm whales stranded on European coasts at the end of the sixteenth and beginning of the seventeenth centuries. One of these illustrates a whale caught in the port of Ancona in 1601, 56 feet long, 33 feet in girth; the scene is an active and lively one, representing a landscape, fishing-boats, men engaged in cutting up the whale, spectators, &c. The Netherlands seem to have had numerous specimens stranded. These, like those occasionally visiting the Scottish coast, are all males, which, when fully grown, appear to go singly in search of food. Other whales, as cachalots, visit the south in larger numbers. Over thirty cachalots, mostly females, were stranded in 1784 in the Bay of Audierne, department of Finisterre; and a school visited Citta Nuova, in the Adriatic, in 1853.

AMERICAN JURASSIC DINOSAURS.—Prof. O. C. Marsh publishes in the current number (November) of the *American Journal of Science and Arts* the principal characters of some new species of dinosaurs. On the flanks of the Rocky Mountains a narrow belt can be traced for several hundred miles, which is always marked by the bones of gigantic dinosaurs. The strata consist mainly of estuary deposits of shale and sandstone, and the horizon is clearly upper Jurassic; the dinosaurian remains in this series of strata are mostly of enormous size, and indicate the largest land animals hitherto known. One new species (*Atlantosaurus immanis*) must have been at least eighty feet in length and several others nearly equalled it in bulk. With these monsters occur the most diminutive dinosaurs yet found, one (Nanosaurus) not being larger than a cat. Some of these new forms differ so widely from typical dinosauria that Prof. Marsh has established a new sub-order to receive them, called Sauropida, from the general character of the feet. They are the least specialised forms of the order, and in some of their characters show such an approach to the mesozoic crocodiles as to suggest a common ancestry at no very remote period. In them the front and hind limbs are nearly equal in size; the feet are plantigrade with five toes on each foot. The carpal and tarsal bones are distinct; the precaudal vertebræ contain large, apparently pneumatic cavities; the sacral vertebræ do not exceed four, and each supports its own transverse process. The pubic bones unite in front by a ventral symphisis; the limb bones are solid. One of the species described and partly figured in Prof. Marsh's paper is called *Morosaurus grandis*; when alive it was about forty feet in length; it walked on all four legs, was probably very sluggish in its movements, and had a brain proportionately smaller than any known vertebrate.

ZOOLOGICAL STATION AT TRIESTE.—It may not be generally known that the University of Vienna in addition to having a zoological establishment in Vienna, has also founded a zoological station on the borders of the Adriatic Sea at Trieste. The general director of both is Prof. Dr. Claus. The assistant at Vienna is Dr. C. Grobben, and the inspector at Trieste is Dr. Ed. Graeffe. As a first fruits of these two excellent establishments Prof. C. Claus has published Part 1 of a handsome 8vo volume entitled "Work Done at the Zoological Institute of the Vienna University and at the Zoological Station in Trieste." The work done consists of 1. A very exhaustible memoir, by Dr. Claus, on a new species of Halistemma (*H. tergestinum*), with remarks on the minute structure of the Physophoridæ. This memoir is illustrated by five folding plates. 2. Contributions to our knowledge of the male reproductive organs in the Decapod Crustacea, with remarks on their comparative anatomy as compared with the same organs in the rest of the Thoracostraca, by Dr. C. Grobben, with six folding plates. 3. On the origin of the nervous vagus in the Selachians, with special regard to the electrical lobes in Torpedo; this is illustrated with woodcuts and one plate. The University of Vienna and Prof. Claus are indeed to be heartily congratulated at these first results from their new institution.

GEOGRAPHICAL NOTES

AT the meeting of the Royal Geographical Society on Monday last, a paper on "Usambara, East Africa, and the Adjoining Country," was read by the Rev. J. P. Farler, who has spent the last three years there in connection with the Universities' Mission. Usambara is described as the Switzerland of Africa, and forms a link in the great East Coast range, which extends from Abyssinia to Natal; roughly speaking, it lies between S. lat. 4° 20′ and 5° 25′, and E. long. 38° 20′ and 39° 10′. The mountains form four detached lines running due north and south, and rising in the higher peaks to about 6,000 feet above the sea-level. The range was evidently thrown up by volcanic action, and consists of granite mixed with spar, with sandstone in the lower spurs containing plumbago. Mr. Farler describes the scenery as varied and beautiful, now soft valleys and hill-sides with hanging woods, now again wild ravines with precipitous cliffs of bare granite. Usambara is drained by four rivers: the Zigi, with its affluent, the Kihuwi, the Mkulumuzi, the Ukumbini, and the Luari, the two first-named emptying into Tanga Bay; none of the four, however, are navigable. Trees are found in the region in great variety, but mostly of stunted growth; euphorbias, fan-palms, and mimosa thorns are seen everywhere, and occasionally baobabs, tamarind-trees, and clusters of the Borassus palm; there is also a kind of wild palm-tree. Various animals are found in the Mjika, or wilderness—antelopes varying from the size of a cow to that of a small goat, gazelles, lions, leopards, hyænas, and large apes. Mr. Farler mentions a noteworthy peculiarity in regard to the River Mkulumuzi, which in the rainy season becomes a torrent: "The stream has cut a deep bed for itself in the granite sides of the mountain, and exploring this bed in the dry season, I have found perfectly round, well-like basins in the rock, varying from a foot in diameter and depth to 10 feet in diameter, and from 8 to 12 feet in depth. There is always a stone at the bottom of these basins, and they must have been formed by the torrent giving, during the rainy season, a rotary motion to the stone." The soil throughout Usambara is a red disintegrated clay upon a granite and sandstone foundation, and covered with a rich vegetable loam; the bottoms of the valleys contain beds of alluvial clay. Probably no more fertile soil could be found in the world, and it is capable of producing every tropical plant. The flora of the region is extensive; in the forests are found ebony, copal, teak, acacia, the india-rubber tree,

the orchella weed, the betel-pepper climber, prickly smilax, with several varieties of the strychnos tree, and many other trees producing valuable wood. The inhabitants are many of them rather Semitic than Negro in their type, having high foreheads, while the prognathous jaw and spur heel are both wanting. They average 5 feet 7 inches in height, are strong, though not robust, and in form and figure resemble bronze statues. After describing the curious marriage customs of these people Mr. Farler concluded with some interesting remarks on the Masai country, which, sooner or later, must be thoroughly explored, so as to obtain a short route from the coast to the Victoria Nyanza.

At the same meeting Sir Fowell Buxton, at the special request of Sir Henry Rawlinson, gave an account of the progress of the road-making experiment from Dar-es-Salaam to the north end of Lake Nyassa. The work does not appear to proceed very rapidly, for but forty miles of road have been made in over twelve months, but it is satisfactory to learn that the natives give no trouble and willingly take to the good road provided for them; as, however, they still persist in their old habit of walking in Indian file, their traffic does not do much towards keeping down the rapidly growing vegetation.

It is now definitely settled that the Earl of Dufferin will preside at the meeting of the Geographical Society on Monday, December 9, and as an appropriate compliment to his lordship's early experiences as a traveller, the evening will be devoted to Arctic matters. We understand that the papers to be read will include an account of the Swedish Arctic Expedition now being so successfully carried out by Prof. Nordenskjöld, a review of the work done by the recent Dutch Arctic Expedition, suggestions as to the best route for future exploration, &c.

From a letter of Prof. Nordenskjöld's, published by Mr. Oscar Dickson, the liberal patron of the North-East Passage Expedition, we learn that during the short stay of the *Vega* at Vaigatz Island the scientific staff did some good work on the fauna of the sea and the flora of the land. A large collection of fishes was made, and special attention was given to Arctic phanerogamous plants. Nordenskjöld himself made some important purchases of "idols" from the Christianised Samoeides, who, notwithstanding their baptism, worship and sacrifice to their old divinities.

We have been favoured by a correspondent with the following extracts from a letter lately received from Mr. Carl Boch, who is exploring and collecting in Sumatra:—"I have been collecting for a month in the highlands of Mount Sago, and, considering the very bad weather, have been successful. My hut is on the south-eastern slope of the mountain, at an elevation of about 4,000 feet above the level of the sea. The mountain is about 8,000 feet high, and covered to the top with virgin forest. In about a week I purpose going on to Siedjoendjoeng, a place noted for its tigers, tapirs, and elephants, and said to be in every respect the best district for a naturalist. At Ayer Muntjer I met the celebrated Italian traveller, Signor Beccari, and stayed with him three days."

The Emperor of Austria has conferred the Order of the Iron Crown upon Drs. Gerhard Rohlfs and Georg Schweinfurth, the celebrated African travellers, and upon Drs. Alfred Brehm and Eugen von Homeyr, the well-known ornithologists.

The well-known African traveller, Dr. Nachtigal, has been elected president of the Berlin Geographical Society.

The *Russische Revue*, as referred to in Behm's monthly summary, contains some further details of Mushketow's recent exploration of the Pamir Mountains. He ascertained that the Pamir consists mainly of granite, metamorphic clay, and mica slate, covered with beds of triassic formation; at least in the northern part or Pamir Chorgosh. The direction of all the granite outcrops is that of the general direction of the Thian Shan, viz., east-north-east, or nearly so. North of the Pamir the granite soon ceases, and in the Trans-Alai Mountains diorite predominates, which takes the eastward direction of the main axis of elevation of the Trans-Alai Mountains, and forms the highest summits, which, as in Kaufmann Peak, reach a height of 25,000 feet. Further north, secondary formations prevail, with great diluvial accumulations. In the region explored by him M. Musketow could recognise no meridional elevation such as could favour the hypothesis of a meridional mountain-system, as was assumed by Humboldt.

In an article on foreign trade with Western China, contained in a recent issue of the *China Overland Trade Report*, we find some interesting notes on the intention of the Russians to push their trade southwards from the Siberian frontier. For this purpose a great commercial station is to be founded in the south-east of the province of Semipalatinsk—probably at the town of the same name, which is well situated for such a purpose, and is even now one of the chief commercial centres of Siberia. It occupies a good site on the east bank of the Irtisch, one of the most important rivers of Siberia, and has a population of several thousands. There are also many Tartar merchants in the place engaged in trade with the Chinese frontier towns in the north, Bokhara, Tashkend, &c. The Semipalatinsk caravans carry southwards printed Russian goods, copper, iron, and hardware, and return with tea, silk, dried fruits, &c. The warehouses of Semipalatinsk also contain carpets from Persia and Bokhara, costly silks and shawls embroidered with gold, ornaments and porcelain from China, diamonds, rubies, and emeralds, together with curiosities and jewellery of various kinds. There is likewise a large trade in cattle, herds of 4,000 or 5,000 being driven into the town by Kirghiz at one time; more than two million sheep are also sold there every year, most of them being forwarded on to Ekaterineburg, where they are killed and the fat used in the great candle-works of the town. It is thought possible that the Russians may intend to hold at Semipalatinsk the great *Yermak* or fair, which now takes place at Irbit, on the frontier, and to induce Chinese and Thibetan traders to go there.

An excellent little book has just been published by Hartleben, of Vienna. Its title is "Malta; Geschichte und Gegenwart, by Herr A. Winterberg. The work consists of three principal divisions. The first gives an exhaustive and well-written account of the topography, climate, position, and political division of the Maltese Islands, besides describing the agriculture, industry, commerce, and institutions of the little country. It closes with an interesting chapter on the physical and moral condition of the inhabitants. The second division treats of the islands from a military point of view, and contains minute descriptions of the fortifications, the various towns and villages, the harbours, bays, sources, and grottoes of the island. The final division, by far the most elaborate, is an ably-written summary of the history of Malta, which in its closing chapters has the additional interest of "showing us ourselves as others see us." The little book contains eighteen illustrations and two neatly-finished maps.

The first article in the November number of Petermann's *Mittheilungen* (it still retains the name) is on the use of elephants in African exploration, by the late editor, and was found on Petermann's table on the evening of his death. The number contains besides a short account by Dr. Miklucho Maclay of his visit to some of the Pacific Islands and New Guinea, and a paper by the same on Volcanic Phenomena on the north-east coast of New Guinea; an account of Bernoulli and Cario's travels in Guatemala and South Mexico in 1877; the

conclusion of Dr. C. E. Jung's Contributions to the Geography of Victoria; an important paper, with map, on the Chinese province of Kwang-tung and its people, by Herr J. Nacken; another on D'Albertis' New Guinea Exploration, with map of the Fly River; with papers on the Exploration of the Ogowé, Nordenskjöld's Voyage in the *Vega*, and Dr. Behm's monthly summary. Thus it seems that Dr. Behm, the new editor, is likely to maintain the reputation and value of this, the most important geographical organ.

THE October *Bolletina* of the Italian Geographical Society contains a short account of the Progress of the Italian African Expedition, and letters from Lieut. Bove who accompanies Prof. Nordenskjöld in his North-East Passage Expedition. In the *Bulletin* of the Paris Society is a translation of the Grand Duke Nicholas's paper on the Shortest Route for a Railway to Central Asia; a paper by M. L. Simonin on the Indians of the United States, with a map showing the Indian reservations; the continuation of Dr. Decugis' Account of his Journey in Morocco; a long article by the Abbé Ménager on Guinea, besides shorter papers on a Uniprojectional Atlas, and the Rio Casca of Peru.

THE Portuguese African expedition, under Serpa Pinto, which left Benguela a year ago, reached Bihé in March last, and was to enter the unknown interior in two divisions. The Lisbon Geographical Society are moving Government for a scientific expedition into Portuguese Senegambia.

ON SOME IMPROVED METHODS OF PRODUCING AND REGULATING THE ELECTRIC LIGHT[1]

AMONG the manifold functions which the elementary substance carbon performs in organic nature, not the least important is that by which it becomes the great source of artificial illumination, whether derived from oils, coal gas, or from coke rendered incandescent by the action of powerful electric currents. Since the time when Davy first produced the voltaic arc, between two points of wood charcoal, through which was transmitted the current from the great battery of 2,000 plates belonging to the Royal Institution, many experiments have been made to determine the best kinds of carbon for developing the electric light. The carbon which, until recently, was most commonly employed for this purpose, is obtained from the sides of gas retorts, where it accumulates in the form of coke during the destructive distillation of coal. The shells of coke from the retort are sawn up into pencils from one quarter to half an inch square, and from six to nine inches in length. Although very good results are obtained from carbon of this kind, it is a difficult material to work on account of its hardness, and it sometimes contains impurities which interfere with its conductivity. It is also liable to fracture when suddenly heated by the transmission of powerful electric currents. These defects have led to the introduction in electric lighting of artificial carbon, composed of powdered coke and lampblack, formed into a paste with molasses and gum. This material is pressed into cylindrical forms, and subjected for a given time to a high temperature in a special furnace. The manufacture of these carbon pencils has attained great perfection in the hands of Carré, of Paris, and they can be made into perfectly straight and cylindrical forms of from two to sixteen millimetres in diameter, and half a metre in length.

When the electric light is to be used for illumination, it is necessary that it should be as continuous as other modes of lighting. For this purpose not only should the current be regular in its action, but the distance between the carbon points must not alter, which necessitates the use of some arrangement for bringing them nearer together in proportion as they are consumed. Much ingenuity has been displayed by electricians in solving this problem, and the automatic contrivances invented by Staite, Duboscq, Foucault, Serrin, and others, leave little to be desired in regard to the steadiness of the light, when the regulators are in good order, and in the hands of intelligent operators. All automatic instruments, however, from the delicacy of their mechanism, are liable to derangement, and their action is not easily understood by persons not having a special knowledge of their construction. To obviate the objection to the use of such instruments by unskilled attendants, I devised, a few years since, a regulator for use on H.M.'s ships of war, to be actuated by hand. In this arrangement the carbons are made to approach and separate from each other by means of a right and left-handed screw connected with the carbon holders. Each of the screws, with its carbon holder, can be actuated independently of the other, for the purpose of adjusting the points of the carbons to the proper focus of the optical apparatus used in connection with it. The regulator, with its carbon points, is placed in the focus of a dioptric lens, which parallelises the divergent rays of light into a single beam of great intensity. The lens with the regulator is pivoted horizontally and vertically on the top of a short iron column, fixed on a raised platform above the deck, and the beam of light may be projected upon any distant object within its range. This special application of the electric light, however, as will be seen, requires the frequent adjustment of the carbons by the operator, but as he is always required to be in attendance to manipulate the projector, no inconvenience is experienced through the absence of the automatic arrangement. This method of regulating the electric light has now been in use in the Royal Navy for more than three years, and has proved very satisfactory.

Simultaneously with the progress of improvements in the mechanism for regulating the electric light, experiments have been made with the object of dispensing with the regulator altogether. The most recent, as well as the most successful, of these attempts has been made by M. Jablochkoff, a Russian inventor. In the specification of his letters patent of 1877 he proposes to place the carbons side by side (as had been previously proposed by Werdermann in 1874), and to separate them by an insulating substance to be consumed along with the carbon. The inventor states that the insulating substance for separating the carbons may be kaolin, glass of various kinds, alkaline earths, and silicates, which he prefers to apply in the form of powder rammed into an asbestos cartridge-case containing the carbons. A powder which the inventor found serviceable consists of one part lime, four parts sand, and two parts talc. These materials are rammed into the cartridge-case surrounding and separating two parallel sticks of carbon placed in the case, at a little distance apart. One of the carbons is made thicker than the other to allow for its more rapid waste. The lower ends of the carbons are inserted into pieces of copper tube or other good conductor, separated from one another by asbestos, and the ends of the tubes are pinched between two limbs of a screw vice, connected respectively to the conducting wires. This combination of carbons and insulating materials the inventor terms an electric candle, which, when mounted on a stand or candle-stick, has the appearance of the Roman candle of pyrotechnists. The inventor further states that the heat produced by the electricity fuses the material between the carbons and dissipates it; and the freedom of the passage afforded by the fused material to the electric current permits the subdivision of the light by placing several lamps in the course of one electric circuit. It is also stated that the construction of the candle may be varied; and, among the forms described, is one in which the carbons, instead of being contained in a cartridge case,

[1] Paper read by Mr. Henry Wilde at the Manchester Literary and Philosophical Society, October 29.

are separated by a partition of kaolin or other similar insulating material.

I have thought it well to describe, as nearly as possible in the words of the inventor, the electric candle, which is now the subject of so much attention in its application to electric lighting; so that its relation to what follows may be more clearly perceived. A remarkable peculiarity of the direct current in electric lighting is that of its consuming the positive carbon at twice the rate of the negative one, and while the negative carbon is a pointed cone, like that of a pencil, the positive pole takes the form of a hollow cavity or crater.

M. Jablochkoff's early experiments seem to have been made with the direct current, and hence his carbons are described as being of unequal thickness, in order that the positive and negative carbons of the candle might be evenly consumed. When the alternating current is used for producing electric light both carbons are of the same thickness, and are consumed at an equal rate, and both points terminate in regular cones. This property of the alternating current, besides other advantages, always maintains the luminous point in the focus of any optical apparatus used in connection with it, that is, when the carbons are placed end to end, as I had occasion to point out in a former paper read before the Society in 1873, on an electro-magnetic induction machine for producing alternating currents.

M. Jablochkoff, in the course of his experiments, would appear to have met with some difficulties in adapting the direct or continuous current to a system of lighting with his electric candles, and now uses the alternating current for this purpose. The candle has also been simplified by substituting a slip of plaster of Paris for the cartridge and partition of kaolin formerly employed.

To produce the alternating currents, however, to supply a number of lights, it was found necessary to employ powerful electro-magnetic induction machines, excited by the currents from other smaller machines, according to the principles laid down in my paper read before the Royal Society, and published in the *Philosophical Transactions* of 1867. From sixteen to twenty lights are produced from one of these electro-magnetic machines, each light absorbing about one-horse power.

The system of electric lighting above described would now seem to be definitely established in some places as a substitute for gas, and visitors to the French capital during the present summer will have been struck with the fine effects produced in the avenues and squares where the light is displayed.

My connection with the history of this system of lighting placed me in a position to make some experiments with the Jablochkoff candle, and led to the discovery of the following facts. One of the conditions necessary for producing a constant light from the candle, in its most recent form, was that the quantity and intensity of the alternating current should be such that the carbons consume at a rate of from four to five inches per hour. If the electric current were too powerful, the carbons became unduly heated, and presented additional resistance to the passage of the current; the points at the same time lost their regular conical form. If, on the other hand, the current were too weak, the electric arc played about the points of the carbons in an irregular manner, and the light was easily extinguished by currents of air.

In the course of these experiments I was struck with the apparently insignificant part which the insulating material played in the maintenance of the light between the carbon points; and it occurred to me to try the effect of covering each of the carbons with a thin coating of hydrate of lime, and mounting them parallel to each other in separate holders, and without any insulating material between them. The use of the lime covering was intended to prevent the light from travelling down the contiguous sides of the carbons. On completing the electric circuit the light was maintained between the two points, and the carbons were consumed in the same regular manner as when the insulating material had been placed between them.

Two plain cylindrical rods of carbon three-sixteenths of an inch in diameter and eight inches long, were now fixed in the holders parallel to each other, and one-eighth of an inch apart. The strength of the alternating current was such that it would fuse an iron wire 0·025 of an inch in diameter and eight feet in length. On establishing the electric current through the points of the carbons by means of a conducting paste composed of carbon and gum, the light was produced, and the carbons burnt steadily downwards as before.

Four pairs of naked carbons mounted in this manner were next placed in series in the circuit of a four-light machine, and the light was produced from these carbons simultaneously, as when the insulating material was used between them. The light from the naked carbons was also more regular than that from the insulated ones, as the plaster of Paris insulation did not always consume at the same rate as the carbons, and thereby obstructed the passage of the current. This was evident from the rosy tinge of the light produced by the volatilisation of the calcium simultaneously with the diminution of the brilliancy of the light from the carbons.

The only function, therefore, which the insulating material performs in the electric candle, as shown by these experiments, is that it conceals the singular and beautiful property of the alternating current to which I have directed attention.

As I have already said, the strength of the alternating current must bear a proper proportion to the diameter of the carbons used, and when a number of such lights are required to be produced in the same circuit, the quantity and property of the current will remain constant, while the tension will require to be increased with the number of lights.

This simple method of burning the carbons will, I believe, greatly further the development of the electric light, as the carbons can be used of much smaller diameter than has hitherto been possible. They may also be of any desired length, for as they are consumed they may be pushed up through the holders without interrupting the light. One of these developments will be a better method of lighting coal and other mines. In this application the alternating currents or waves from a powerful electro-magnetic induction machine may be used for generating, simultaneously, alternating secondary currents or waves in a number of small induction coils, placed in various parts of the mine. The light may be produced in the secondary circuits from pairs of small carbons inclosed in a glass vessel having a small aperture to permit the expansion of the heated air within. Diaphragms of wire gauze may be placed over the aperture to prevent the access of explosive gas. By generating secondary currents or waves without interrupting the continuity of the primary circuit, the contact-breaker is dispensed with, and the subdivision of the light may be carried to a very great extent.

A STUDY IN MAGNETISM

THE name of Faraday will go down to posterity foremost amongst the names of the scientific men of this century, for the simple comprehensiveness and original beauty of his researches in electricity and magnetism; chiefly, perhaps, for his discovery of magneto-electricity—the kind of electricity that can be induced in conductors which are caused to pass near magnets. Those who have carefully read Faraday's works know how he was led to this discovery by the conception he had formed of magnetic force. Until his time magnetic

attractions and repulsions had been explained as a kind of action-at-a-distance. Faraday explained them as the results of the action of the medium filling the intervening space; and he gave several indisputable proofs that the space surrounding a magnet was thrown into a peculiar condition by the presence of the magnetism. Two centuries previously another Englishman, as uniquely

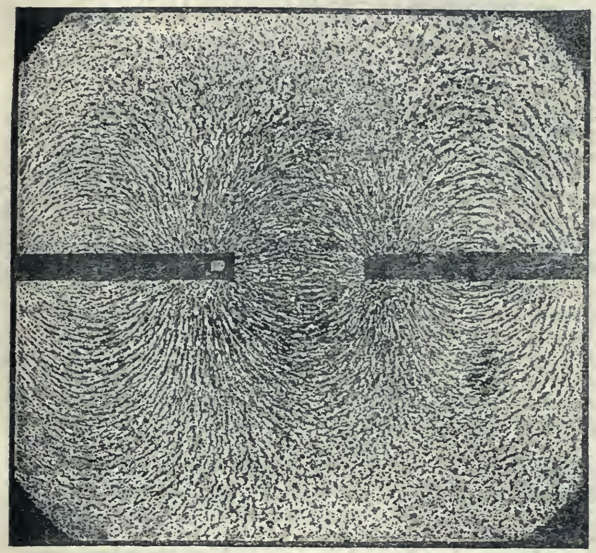

Fig. 1.

great if not greater, Dr. Gilbert, had in his famous treatise "De Magnete," told how iron filings sprinkled on a piece of card beneath which a magnet lay, assumed certain mysterious lines. To these lines Faraday gave the name of *lines of force*, and showed that they represented, wherever they went, the direction and strength of

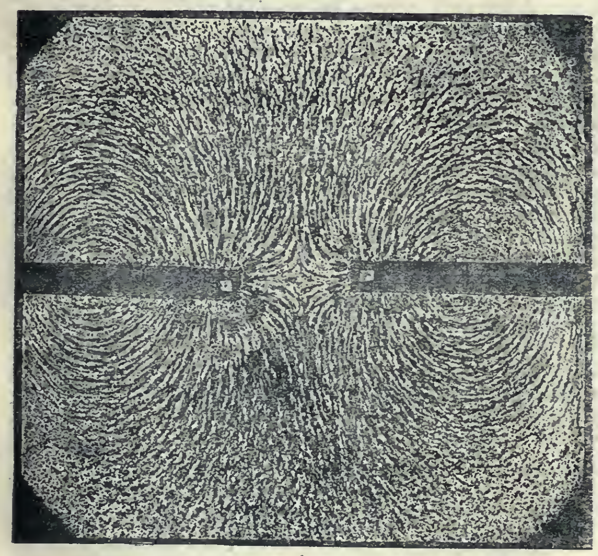

Fig. 2.

the magnetic force. His imagination seized upon these mysterious lines, and he saw all space, wherever a magnet had influence, traversed by them. He perceived that they were in some way bound up with that which was mysterious and unexplained in this seeing action-at-a-distance. He found them to react on one another, and to follow certain definite laws ascertainable by experiment. In the volumes of his researches he filled several entire plates with drawings of the figures assumed by the lines under various combinations. They had taught him to anticipate magneto-electricity and electro-magnetic rotation. He had diligently followed them up from the hint afforded by Dr. Gilbert's experiment with the iron filings. He had begun to apply the method to

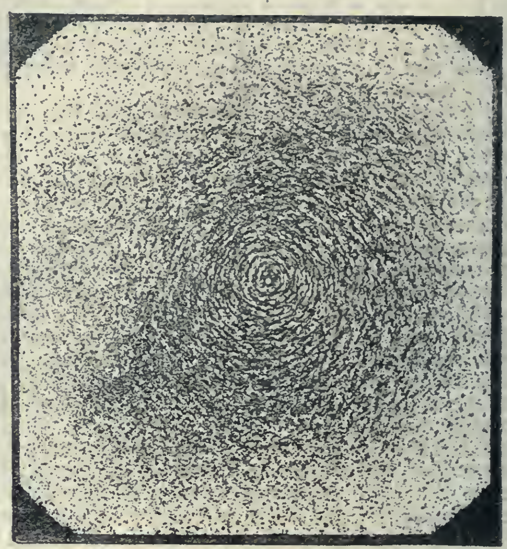

Fig. 3.

the investigation of the interaction of electric currents, when the decay of age overtook him, and the research dropped from his grasp. Had he lived the study which the writer of the present article is about to narrate would have been completed long ago.

The experiment of laying a card or a sheet of paper

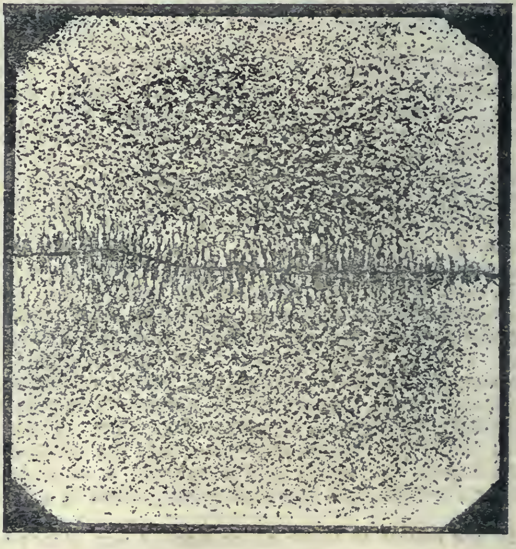

Fig. 4.

upon a magnet, sprinkling over it fine iron filings, and then tapping the card gently so as to allow the filings to take up their places in the "curving lines of force," is one which always possesses a peculiar interest and fascination for youthful electricians. Two other experiments, due originally to Musschenbroek, are not quite so familiar, though they are as simple; and since they have

a special bearing on that which follows, we will mention them in detail.

Let two bar-magnets of steel be placed on the table with the north-seeking pole of one towards the south-seeking pole of the other, but not touching. Over these lay a sheet of stiff writing-paper, or card, or a sheet of window-glass. Fill a pepper-box with fine iron-filings,

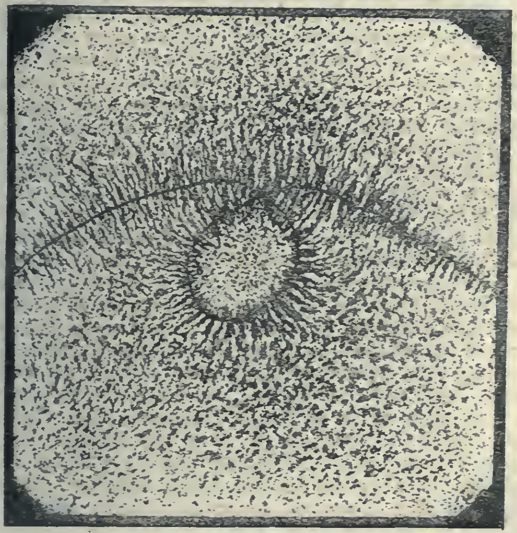

FIG. 5.

and sprinkle them evenly over the sheet; then tap the sheet gently, until the filings have arranged themselves. Observe (Fig. 1) that the lines of force run across from pole to pole. A line of force represents the direction in which the forces act. Suppose that the pole on the right is the north-seeking pole, and that on the left a south-seeking pole. The forces act across the space between them in

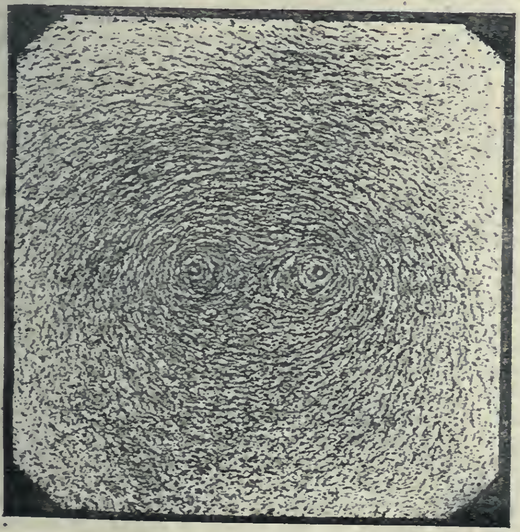

FIG. 6.

the continuous curves from pole to pole. Suppose you could obtain a piece of steel imbued with magnetism of one kind of polarity only—a magnetic "particle," in fact, of the same kind of magnetism as the north-seeking pole. If you were to put that magnetic particle down on one of these lines near the north-seeking pole on the right, it would, as we know, be repelled away, since similar poles repel one another. And it would move away along the line of force (for that line of force represents the direction in which the force acts), and would pass right over and be attracted to the south-seeking pole on the left. Similarly a magnetic particle of south-seeking polarity, if we could get one and place it down on a line of force, would be driven along the line in the opposite direction.

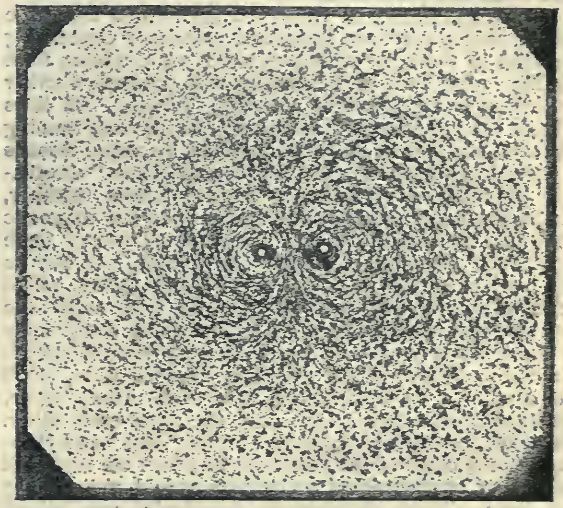

FIG. 7.

Notice, too, that a great many of the lines of force that run out of one pole run into the attracting pole opposite. This you will find always to be the case when two poles attract: their lines of force run into one another.

As a second experiment lay down the two magnets, but put their north-seeking poles towards one another, and then lay on them a sheet of card or glass, and sprinkle

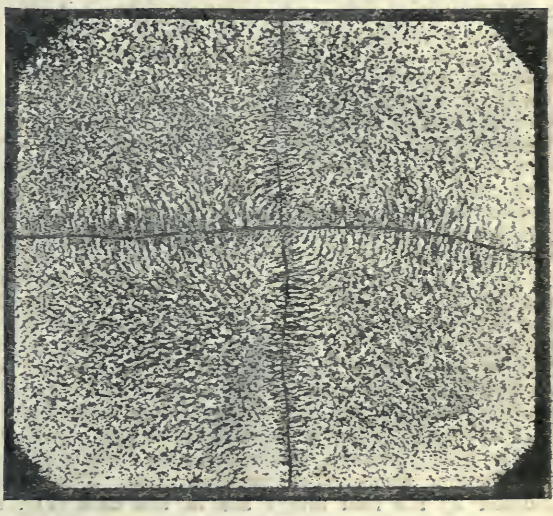

FIG. 8.

filings over, as before. The curves you obtain, which are like those of Fig. 2, are quite different from those obtained before. This time the lines do not run across from pole to pole. They start out, but instead of uniting and blending together, and bending over to run into one another, they turn away sharply where they encounter one another, and, without ever joining, swerve aside in

almost parallel paths. If our supposed particle of north-seeking magnetism were placed on a line near one pole it would not pass over from pole to pole, but would follow the line where it swerves away to the side. We know (by experiment) that two north-seeking poles repel one another, and we see here that the lines of force of two such poles never run into one another, but turn aside mutually repellant. You will find that this is always the case when two poles repel.

Such experiments as these led Faraday to enunciate several simple yet most important principles concerning the lines of force, by means of which we can learn from the lines what kind of action they will produce, whether attraction, or repulsion, or rotation. *Firstly.*—All lines of force tend to shorten themselves. If the lines running across in our first figure were replaced by actual threads of stretched elastic material, we see that any "shortening" of them would bring the poles nearer together, which, indeed, is precisely the tendency of the magnetic attraction between the poles. *Secondly.*—Lines of force repel each other when placed side by side. If this be the case then the lines in our second figure, which bend outwards, and run off side by side, repel one another, the two poles must be experiencing a tendency to move away from one another; and this we know is the case. *Thirdly*, Like magnetic lines of force, when "end on" to each other, run into each other; while, unlike magnetic lines, when end on, repel each other. Here, of course, we apply the terms "like" and "unlike" to the cases of the directions in which our supposed particle of north-seeking magnetism would move along the lines. These notions of Faraday's are full of meaning, and it is not many years since Prof. Clerk Maxwell showed how well they agreed with the most perfect mathematical expression of the forces that operate in the medium filling the surrounding space.

Keeping these simple principles in mind, let us apply them to some further cases of magnetic action, and see if they are equally applicable. We know that the wires carrying electric currents possess certain magnetic properties, and will deflect magnetic needles; that two electric currents may attract or repel each other; and that current may make a magnet pole rotate round it. Can we explain such electrodynamic actions also by applying the principles of Faraday to the magnetic lines of force existing in these various cases?

In the first place, what are the lines of force belonging to a wire through which an electric current is passing? To ascertain this we will bore a hole through a card or a piece of glass, and pass a wire up through the hole. Then, joining the ends of the wire to the poles of a powerful battery, we will, while the current is passing, sprinkle on iron filings, and, tapping lightly, will permit them to assume their places in the lines of force. Fig. 3 was thus obtained. It shows us a series of concentric circles. If a supposed north-seeking magnetic particle were put down on one of these circles it would move round and round in one direction; supposing the current to come up through the hole, this direction would be opposite to that of the hands of a watch. If the current went down through the hole, the movement would be the other way round. But we may examine the current in another way. Lay the conducting-wire down flat, and place over it the card or piece of glass. The forms assumed by the iron filings are in this case (Fig. 4) straight lines across the wire—are edge-views, so to speak, of the systems of circles we just now obtained.

These two figures were discovered by Faraday, and are given in his researches. They are also given by Dr. F. Guthrie in his book on "Magnetism and Electricity."

If we wind up our conducting-wire into a simple knot or loop, carefully preventing the overlapping parts from touching, the figure obtained with the iron filings is like that of Fig. 5. It is interesting to observe how in the middle of the loop there are no lines, only dots. The lines of force run through the loop, perpendicularly to its plane, and we only see them end-ways as points. It is clear that a magnetic particle such as we have imagined would be either attracted into the middle of the loop, or would be repelled out of it, according to its polarity.

Now what is the effect of carrying two parallel currents through two wires side by side? Take a piece of card or glass, as in Fig. 6, having two holes in it; through these pass a couple of wires joined to two batteries, so that the two currents are either both ascending or both descending through the flat surface. The magnetic field mapped out by the iron filings will then show a series of curves, the outermost of which are rough ovals inclosing both the currents, whilst the innermost are small ovals round each wire. The lines between the inner and outer systems present a sort of hour-glass shape or *lemniscate.* Had the two parallel currents, however, passed in opposite directions through the plate, one ascending and the other descending, the filings in the magnetic field would have taken the form given in Fig. 7. Here we find two separate systems of distorted and flattened circles surrounding the wires, each separate system of circles having displaced the other. The outer curves do not run into each other as in the preceding case. Let us apply Faraday's principles to these two figures. In the former (Fig. 6) any "shortening" of the exterior lines would tend to draw the centres nearer together. In the latter case (Fig. 7) no such consequence need result. A tendency of the successive lines to repel each other and to maintain equal distances from each other, would in the former case tend to reduce the entire figure to a system of concentric circles, which could not be accomplished unless the two centres approached each other and coalesced. In the latter case, since the systems of lines round the two centres never join across, this tendency would have the result of driving the two centres far apart to allow of the lines becoming perfect sets of circles. Now we know from Ampère's classical researches on parallel currents, that they attract one another when they run in the same direction, but are mutually repellant when they run in opposite directions. Our application of Faraday's principle enables us to foresee this electro-dynamical action as a consequence of the distribution of magnetic force in the field. In an exactly similar manner we may reason out the action of the forces in the field which is produced by two currents crossing one another at a right-angle (Fig. 8), the conducting wires attracting one another across those quadrants in which the currents flow both towards or both from the point of intersection.

We may apply our study further and investigate, with iron-filings, the action which currents exert on magnets. Let us conduct a current vertically through a hole in a plate, and fix near it a small magnetic needle, as in Fig. 9. The needle has been placed so as to point with one pole towards the current. The lines of force radiating from that pole run round and coalesce on one side with the circular lines of force of the current. On the other side of the pole they absolutely refuse to unite with the circles, and repel them away. Clearly, the "tendency to shorten," which Faraday predicated of the lines, would drag the pole of the magnet in one direction round the current. Looking at the other pole of the magnet we see that the tendency acts in the opposite direction, so that the total result would be a tendency to turn round the magnet about its middle point, and set it at right angles to its present position. This consequence, too, is, as we know from Oersted's famous experiments, the fact.

If, instead of laying the needle down flat, we had reared it up on end, as in our Fig. 10, where a square black

spot marks the place of the pole, we should perceive that the systems of circles round the current and of rays round the pole mutually disturbed each other, and that the figure was consequently unsymmetrical. Round one half of the figure the lines coalesce ; round the other they repel each other, and stream away. Applying the notions we have already obtained, we see that the result will be a

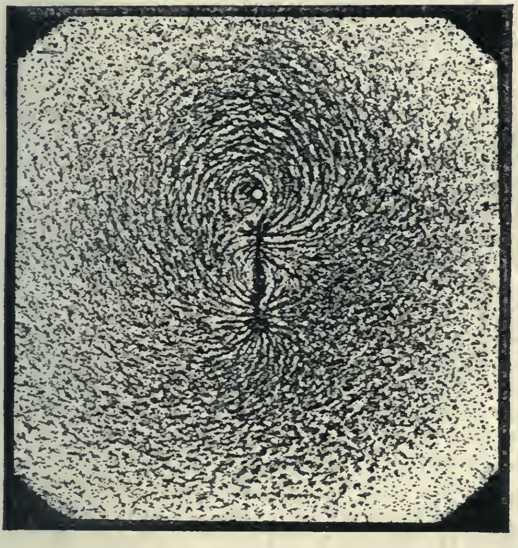

FIG. 9.

force tending to make the pole and the current rotate round each other. This, we know, was shown by Faraday himself to be the case, for when one was fixed and the other free to move, the one rotated round the other. Carry on the idea one stage further, and make the current run up through the plate at the precise point where the pole

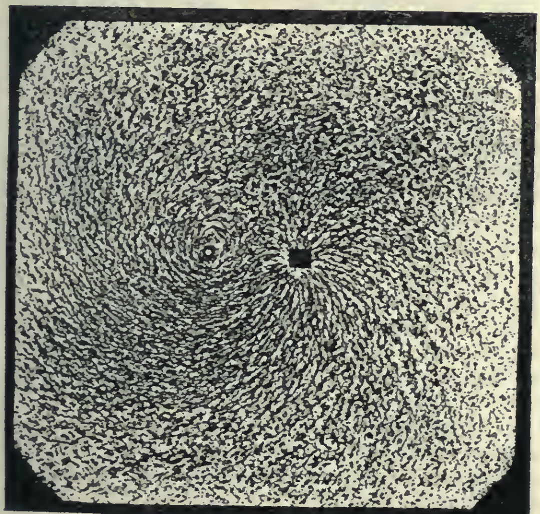

FIG. 10.

of the magnet is. Let it run up through the magnet. The "field" we obtain (Fig. 11) shows us neither the rays of the magnet nor the circles of the current, but a set of beautiful spirals unwinding from a common centre. What kind of motion can we deduce from this remarkable figure? If the branches of the spiral could shorten themselves they would certainly rotate the central region round on itself. The corresponding fact exists in another of Faraday's discoveries: that a magnet can be made to rotate round its own axis, under the influence of a current running up it through one of its poles.

One experiment more will close for the present our

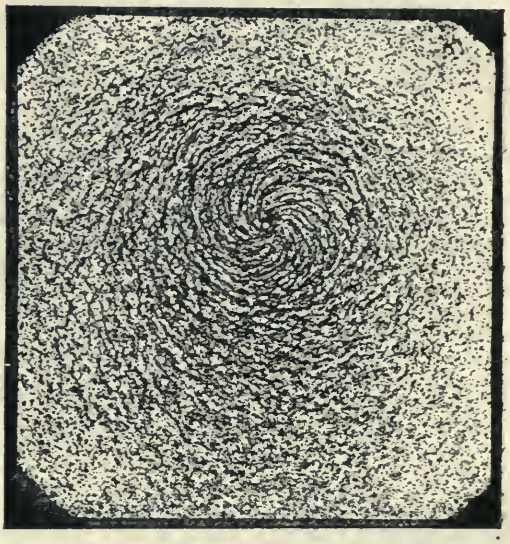

FIG. 11.

study in magnetism. We know that a rod of iron becomes a magnet when we wind a spiral of wire round it and send a current through the wire. There must be some relation between the iron bar and the coils of wire: what is it? Let us investigate this also by looking at the distribution of the lines of force within the coil.

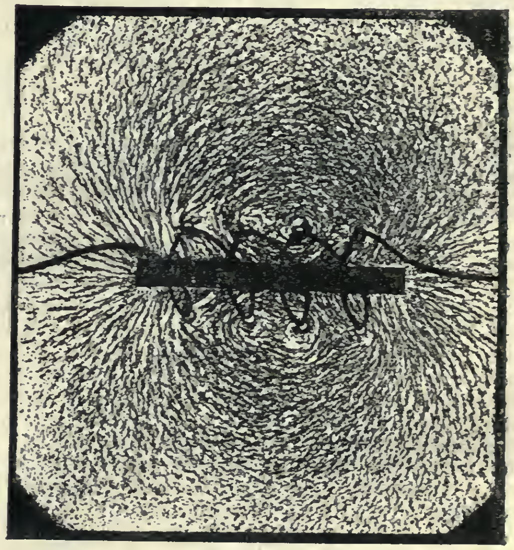

FIG. 12.

Take a plate of glass or a piece of card and bore eight holes through it, as in Fig. 12, and wind a corkscrew of wire in and out ; then lay a little bit of thin, soft iron down the middle. We see by the lines of force, when the current is passed, that the iron becomes a strong magnet, but that the wires at the same time are mag-

netic also. We shall discover also that the magnetism of the little iron bar is not distributed exactly in the same way as if it had been a permanent steel magnet, for the lines of force follow curves that fill surrounding space slightly differently. Still, on the whole, we should argue that the iron core possessed magnetic poles where the force was greatest, and that the two poles were of opposite kinds of polarity, one being a north-seeking, the other a south-seeking, pole.

SILVANUS P. THOMPSON

THE LATE MR. G. DAWSON ROWLEY

IT is with sincere regret that we have to announce the death, on the 21st inst., at his house in Brighton, of Mr. George Dawson Rowley, the projector of, and principal contributor to, the *Ornithological Miscellany*, which he published at his own very considerable cost, and author of several papers on ornithological and archæological subjects. Educated at Eton and Trinity College, Cambridge, where he graduated B.A. in 1846, he was the companion, both at school and at the University, of the late John Wolley, whose early passion for natural history he shared. In Mr. Rowley, however, the taste for a time gave way to antiquarian studies, and did not return, at any rate very strongly, until some years afterwards, when he had married and was settled at Brighton, where, notwithstanding the *dictum* of Mr. Ruskin that "no English gentleman has ever thought of birds except as flying targets or flavorous dishes," he became, so far as the opportunities of the place allowed, a very watchful observer of all that was passing in the feathered world, while in the spring he yearly repaired to his father's estate at St. Neot's in Huntingdonshire, the better to study the habits of birds in the breeding-season. He also began to form a collection of ornithological specimens of singular value, sparing no cost or trouble in the acquisition of objects of rarity or peculiar interest, and the treasures thus amassed finally became very numerous. The design of his *Ornithological Miscellany* seems to have chiefly been to illustrate this "Rarity Chamber"—for so, after the example set by old Rumphius, it might well be called—a considerable number if not most of the specimens therein figured or described being his own possessions. Yet he willingly accorded room in its pages to worthy contributors, among whom may be mentioned Mr. Dresser, Dr. Finsch, Messrs. Salvin, Sclater, Seebohm and Sharpe, and Lord Tweeddale, and his printing a translation of Prjevalsky's important work on the birds of Turkestan, published in Russian, with copies of the plates, was a real boon to those ignorant of that language. Besides this he often wandered into the by-ways of ornithology, which frequently possess a curious kind of interest, and he gave views of many places remarkable for the birds which frequent them. Never did the contents of a work better justify its title, for anything more miscellaneous than they are cannot well be imagined. Failing health, as he himself only a few months ago stated in his concluding remarks, brought it to an end far sooner than he had intended. Setting aside the scientific value of some of the papers, the beautiful plates by which nearly all are illustrated make its cessation a loss to ornithologists; and those who knew that Mr. Rowley had for a long time been gathering information bearing on the history of the extinct Gare-fowl (*Alca impennis*) had hoped that some result of his labours in this respect would one day make its appearance. But this was not to be. More than a year ago a violent hæmorrhage of the lungs gave warning of serious danger, and the attack was only too quickly followed by others of a like nature, under which he sank, in his fifty-seventh year, dying, by a singular coincidence, on the very same day as his father, who had long been an invalid.

NOTES

WE notice with regret the death, at the age of sixty-eight, of Mr. James M'Nab, the well-known curator of the Edinburgh Royal Botanic Garden. Mr. M'Nab's father was also curator of the Edinburgh Botanic Garden, where the son was trained. In 1834 Mr. M'Nab paid a visit to the United States and Canada, the fruits of which appeared in a variety of contributions, descriptive of the more interesting plants found during the journey, in the *Edinburgh Philosophical Journal* for 1835, and in the *Transactions* of that period of the Edinburgh Botanical Society. On the death of his father, in December, 1848, after thirty-eight years' superintendence of the Botanic Garden, Mr. M'Nab was promoted by the Regius Professor (Dr. Balfour) to the responsible post thus vacated. The extent of the Garden at that time was not more than fourteen imperial acres. Ten years later, however, two acres were added on the west side, which were laid out and planted by Mr. M'Nab, under the superintendence of Prof. Balfour. After the lapse of five more years the Experimental Garden, extending to ten acres, was thrown into the Botanic Garden, and planted with conifers and other kinds of evergreens. On a portion of the ground so acquired a Rock Garden was, on the suggestion of Mr. M'Nab, begun towards the end of 1860. The Rockery has now upwards of 5,442 "compartments" for the cultivation of Alpine and dwarf herbaceous plants, and is yearly being added to; while of late years portions of the southern slopes have been set apart for the rearing of bulbous and other plants, whose roots require to be well ripened before flowering. Mr. M'Nab was a frequent contributor to horticultural and other magazines, his writings including papers, not only on botanical subjects, but on vegetable climatology, landscape gardening, and arboriculture. One of the original members of the Edinburgh Botanical Society, founded in 1836, he was a voluminous writer in its *Transactions*; and in 1872 he was elected to the presidency of the society—a position rarely held by a practical gardener. In November of the following year Mr. M'Nab delivered his presidential address on "The Effects of Climate during the last Half-Century with Reference to the Cultivation of Plants in the Royal Botanic Garden of Edinburgh and elsewhere in Scotland," a paper which excited a good deal of discussion at the time, the writer having adduced facts with the view of showing that a change in our climate had taken place during the period in question. Mr. M'Nab also contributed to the Society a monthly report on thermometrical readings and progress of open-air vegetation in the Botanic Garden, which was highly valued, alike by horticulturists and meteorologists, for the practical information it conveyed. Prof. M'Nab, of the Royal College of Science, Dublin, is a son of the late Mr. M'Nab.

ON Friday a meeting of the local executive of the British Association was held at Sheffield to appoint committees to make the necessary preparations for the visit which commences on August 20 next year. The Master Cutler (Mr. W. H. Brittain) presided. It was stated that the guarantee fund now amounted to 3,338*l.*, and would eventually reach 5,000*l.* The Association, however, do not wish the expenses to exceed 1,500*l.*, or they fear that the expense of entertaining the Association will deter other towns from sending invitations. It is expected that at least 1,500 members and associates will attend the sittings. The necessary committees were appointed, and Mr. J. E. H. Gordon, who was present representing the Association, thanked the people of Sheffield for the splendid preparations they were making for the reception of the Association and for the hospitality which was already offered.

M. BARDOUX has appointed a great commission for the reorganisation of the Museum of Natural History of Paris. This

famous institution is almost entirely deserted by students. The report describes all the transformations the Jardin des Plantes has undergone since it was taken out of the hands of the king's physician and entrusted to the care of a special director.

ALTHOUGH we are aware that the columns of NATURE are studied by a considerable number of readers in Australia, New Zealand, and Japan, it is with some pleasure that we find an extract, however incorrect, from one of our articles ("On Cleopatra's Needle and the Wind Pressure"), inserted in the *Bolton Evening News*. Before "A Constant Reader" (we presume of the *Evening News*) took the trouble to multiply out the supposed 80 lbs. to the *square inch*, obtaining the somewhat alarming result of 11,520 lbs. to the square foot for a wind pressure, it might have allayed his fears concerning his own *integrity* and that of the Manchester houses, if he had consulted the original article.

THE Dundee Naturalists' Society have just obtained possession of a very fine specimen of *Pterygotus anglicus*, which was found at Carmyllie Quarries some months ago, and has now been presented to the Society by Messrs. Duncan, Falconer, and Co., the lessees of the quarries. Only fragments of this animal have hitherto been found, and its general appearance has been shown by what are known as restorations; but the correctness of these has been doubted by many palæontologists. This specimen, which is on a slab of the well-known Carmyllie pavement, has from head to tail the segmental plates all intact, with the exception of about an inch of the telson, which is wanting. The length of the fossil is 4 feet 2 inches, and its widest segment 15 inches. The carapace or head plate measures 10 inches by 8, and the telson or terminal plate 8 inches by 7. The abdominal aspect is presented, and the curious arrow-shaped plate, "epistoma," is distinctly shown attached to the middle of the second abdominal segment. In many attempted restorations this plate is figured on the under side of the anterior portion of the carapace.

THE rich collection of insects of Dr. Moritz Isenschmied is bequeathed to the Natural History Museum of Bern, together with a sum of 3,200*l.* for the entomological part of the museum.

A SCIENTIFIC society has been formed at Berlin under the title "Freie Akademie, wissenschaftlicher Centralverein," with the object of propagating scientific knowledge in wider circles by means of lectures. The new society will begin its work in January, 1879. Herr Eberty, the syndic of Berlin, and Dr. Max Hirsch are its directors, and the number of members is rapidly increasing.

AT the instigation of the "Society for the History of the Lake of Constance and its Surroundings," the King of Würtemberg has requested the Statistical and Topographical Office of Stuttgart to undertake a complete investigation of the lake in question. It appears that the various depths of the different parts of the lake have not been measured since 1826. The new investigation will doubtless yield a number of highly interesting data.

AN excellent geological map of Germany has just been published by the Photolithographic Institute of F. Graaz at Leipzig. It is drawn by Prof. Hirschwald, of Berlin, after the relief of C. Raoz, and is specially intended for use at geological lectures.

THE *Times* of yesterday contains an account of Dr. Schliemann's further excavations on the site of Troy, the account being evidently condensed from several letters of the enthusiastic explorer. All Dr. Schliemann's previous conclusions seem to be confirmed, and his already large collections have been greatly added to. Fortunately for his sceptical critics, some of his discoveries have been made in the presence of several British naval officers stationed at Besika Bay. Among other things he has found a steel dagger, the first iron object found on the site, but perhaps the most curious find are "the billions" of shells of cockles and mussels "found in all the strata of the prehistoric *débris*," and said to be no longer found on the shores of the Hellespont and Ægean.

AT some excavations recently made at Heidelberg a Roman well and several milestones were discovered, the inscriptions upon the latter giving interesting details regarding the old Roman colony on the banks of the Neckar.

MR. A. R. WALLACE has reprinted from the *Fortnightly Review* his valuable paper "On Epping Forest and how best to deal with it." It proves how well qualified Mr. Wallace is to have the care of what remains of the once extensive forest.

MR. DE WALL, the *Polytechnic Review* states, has observed that when two electric sparks are simultaneously produced at the extremities of a short tube smoked inside, the two discharges give figures in the form of a black ring at the middle of the tube. When the sparks are not quite simultaneous, the ring is slightly displaced. It is suggested by the author that this observation may afford a method of determining the velocity of sound, and of the speed of propagation of electricity in a conductor.

PROF. PERSIFOR FRAZER reports, we learn from the *Polytechnic Review*, the interesting observation that early in last June he tried a telephone with a diaphragm mounted so as to vibrate freely except in the circular line, where it was bound fast. With several other telephones in circuit, but muffled so that they could not take up the direct vibrations of the voice, he found that the over-tones produced in the diaphragm of one telephone, by a musical note sung into the mouth-piece, were reproduced in the others. This shows the extreme minuteness of the motion necessary to produce sound by fluctuations in the transmitting power of the line wire.

WE are glad to se that the *Princetown Review*, hitherto known as a high-class theological journal, is enlarging its programme so as to include subjects of scientific interest. In the November number, for example, we have excellent papers on "The Rights and Duties of Science," by Principal Dawson; "Man's Place in Nature," by Prof. Le Conte; "Eclipses of the Sun," by Prof. Simon Newcomb; "The Recent Solar Eclipse," by Prof. Young; and "Physiological Metaphysics," by President Ponter. Besides these there are other good papers on a variety of non-theological subjects.

L'Electricité of November 20 contains a first paper by Count du Moncel, on Lacour's Phonic Wheel, and several important papers on Electric Lighting.

THE *Lancet* announces the publication, next week, of a special article, from the pen of Dr. Richardson, on the remains of Harvey. The author has recently visited the church at Hempstead, in Essex, where Harvey lies, and has had photographed all the important historical mementoes, copies of some of which will be reproduced in the *Lancet*. The publication is intended as a further contribution to the literature of the tercentenary year of the birth of the greatest and most original of English anatomists.

AT 6 o'clock on the evening of October 2 a severe earthquake was experienced in the village of Jucuapa and neighbouring towns, in the department of Usulutan, in the southern portion of the Republic of Salvador. Nearly all the houses in Jucuapa were destroyed and many families buried in the ruins, particularly in the outskirts of the town, where the

means of escape were confined to narrow streets, and where the houses were not so solidly constructed as in the centre. The towns included in the disaster are Guadalupe, Nueva Guadalupe, Chinameca, Usulutan, the Caserio del Arenal, Santiago de Maria, which is entirely ruined and some lives lost, a condition in which are also found Tecapa, Triunfo, and San Buenaventura. The shock which produced the greatest damage was at first a kind of oscillatory movement which lasted over forty seconds, and terminated in what felt like a general upheaval of the earth, and was so violent that solid walls and arches and strongly braced roofs were broken and severed like pipe-stems. The movement proceeded from the south-west to the north-east. It was supposed to proceed from the volcano of Tecapa, which is reported as being in conflagration. The district which has been devastated is one of the most thickly settled portions of the country. The *Idea* of Santa Ana reports that apprehensions exist in the public mind that the volcano of Santa Ana is about to be in eruption, from the effects of which serious consequences are feared. The *Panama Star and Herald* is the authority for these statements.

A CORRESPONDENT of the *Pioneer*, writing from Mirzapore, calls attention to a phenomenon which he considers worth recording. Early one morning large quantities of fish of every description were seen coming to the surface along both banks of the river gasping and dying; all the crabs came out and hung in clusters to the clay, or lurked in the grass above the water level, and large eels, leaving the water, lay like snakes along the edge. The next day great numbers of fish, some of enormous size, floated past, and endeavours were made to induce the natives to bring them on shore for manure, but as their fathers had never employed fish for such a purpose, they declined to make such an innovation. The river was high, but not in full flood, and the water, probably on account of the long drought, was intensely and abnormally turbid. The death of the fish is attributed to this peculiarity, for the particles of earth held in suspense appear to have impregnated the gills and stopped breathing; it had not, however, been ascertained which of the affluents of the Ganges or Jumna had caused the mischief.

THE following method of measuring approximately the velocity of sound, devised by M. Bichat (*Journal de Physique*) is said to form a suitable lecture experiment. A white-iron tube, about 10 m. long is bent back on itself, so that the ends A and B are near each other. A is closed with a caoutchouc membrane; B has a stopper with glass tube which communicates, through a caoutchouc tube of a certain length, with one of M. Marey's manometric capsules. Near the end A is an aperture which, by means of another caoutchouc tube the same length as the former, communicates with another of Marey's capsules. These capsules are arranged before a blackened cylinder, the ends of their levers applied to it one over the other. A tuning-fork, giving 100 vibrations per second, inscribes these also in the same vertical line on the cylinder. All being ready a slight blow is given, with the hand or otherwise, to the membrane A, while an assistant turns the cylinder. The capsules register the point of departure and that of arrival, while the tuning-fork gives the time. Thus it is found that, between those two points, there are, *e.g.*, three vibrations of the tuning-fork, *i.e.*, about $\frac{3}{100}$ of a second have elapsed. The velocity of sound is inferred to be 333·3 m. per second. By means of two iron tubes placed one above the other the difference of the velocities of sound in air and hydrogen may be demonstrated, even though it may be difficult to keep the one tube filled with pure hydrogen.

AN historico-ethnographical exhibition has been opened at Winterthur (Switzerland), and the visitors are agreeably surprised by the large number and great variety of objects exhibited as well as by their artistic arrangement.

JAPANESE farmers appear to be determined not to be left behind by their fellow-countrymen in matters of progress, for we hear that in some parts they are growing wheat from foreign seed. On this subject a Nagasaki paper says:—"We have seen a magnificent specimen of wheat grown in Japan from American seed, than which nothing better could be desired, the flour produced from it being fully equal to any we have seen from America. Such a result speaks well for the prospects of Japan becoming, with proper cultivation, a profitable wheat-producing country."

A GERMAN engineer residing at Smyrna, Herr Karl Humann, who some time ago had undertaken some successful excavations at Berghama at his own expense (the ancient Pergamum in Asia Minor), has recently been commissioned by the German Government to continue these excavations, and has succeeded in bringing to light some highly interesting objects of art. The Porte has permitted the continuation of the excavations under the condition that only half the objects found shall become German property, while the other half will be retained at Constantinople.

IN the *Annual Report* of the Royal Botanic Garden, Calcutta, for the year 1877-78, Dr. King, the superintendent, draws attention to the want of proper accommodation for the herbarium, which now consists of ninety-three cabinets of dried plants, forming, as we are told, "the only large herbarium in India, containing authentic specimens from almost every Indian botanist from Heyne to Kurz, including excellent sets of Wallich's, and Hooker and Thomson's plants." Dr. King reports that of the seedlings of the Para rubber plant (*Hevea brasiliensis*) received at the beginning of last year, some were retained at Calcutta, while the others were sent to the Cinchona plantation in Sikkim. Several of the plants have died during the year, but those remaining at Calcutta are healthy, and have grown fairly well. Of the Ceara rubber plant (*Manihot glaziovi*), many of them were found to be dead on arrival; those that survived were divided between Calcutta and the Cinchona plantation, one of the plants is said to be ten feet high, and the others vary in height from two to five feet, but they all appear weak and lanky, as if the climate were too damp for them. Regarding the cultivation of vanilla in India, especially in the climate of Calcutta, Dr. King's experience confirms his first impression that "it is not worth while to go to any further expense in attempting to make a plantation of it, to be conducted on commercial principles." It is satisfactory to learn that ipecacuanha has been propagated largely; like vanilla, Dr. King is of opinion that it can never be grown successfully as a crop in any part of Bengal. The utilisation of new vegetable substances for paper-making, especially baobab bark and bamboo shoots, are fully considered by Dr. King, who expresses an opinion with regard to the former that, if the plant is "to be grown to a profit, it would be hardly feasible to give it cultivation, however rough, after the first year." Considering also the comparatively slow growth of the baobab, Dr. King says he is driven to the conclusion that it is not likely to afford in India a sufficiently cheap paper-fibre. He points out that a plant yielding an annual crop is much more likely to fulfil the financial conditions of success than any perennial like the baobab, which yields a crop only after many years. Regarding the use of the young shoots of bamboo for paper stock, which have been very favourably reported on by Mr. Routledge, Dr. King does not look upon it in any hopeful light. Of the so-called "Rain Tree," which has already been noticed in our columns, and referred to *Pithecolobium saman*, a number of good trees are growing in the Botanic Garden, Calcutta. One set consists of five trees, about eleven years old, and the other of eighty-four trees, planted in an avenue about four years ago. The tree is a very fast grower, and is said to be perfectly at home in the soil and climate of Lower Bengal. From its

umbrageous habit and wide-spreading branches it is extremely valuable as a shade tree. The wood is soft and of little value except as firewood, and the pod is sweet, like that of the carob (*Ceratonia siliqua*), and may probably prove valuable as a food for cattle, for which purpose, indeed, these pods are used in the West Indies. For this reason, and not for that of gathering and dispersing moisture (for which the tree became momentarily celebrated), it is probable the tree may be generally planted.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. Theodore Beck; a Black-crested Cardinal (*Gubernatrix cristatella*), two Red-crested Cardinals (*Paroaria cucullata*) from South America, purchased; a Macaque Monkey (*Macacus cynomolgus*) from India, deposited; a Baker's Antelope (*Hippotragus bakeri*) from Nubia, received in exchange.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE proposals of the Cambridge Mathematical Studies Syndicate for completing the new scheme for the mathematical tripos have been carried. The following summary of the whole scheme of the mathematical tripos which will come into operation in the year 1882 is given in the *Times*. It will consist of three parts, the examination for each part occupying three days. The subjects of the first part are to be confined to the more elementary parts of pure mathematics and natural philosophy, the subjects to be treated without the use of the differential calculus and the methods of analytical geometry. The examination in Part II. will only be open to those who have passed Part I. so as to deserve mathematical honours, and the subjects are algebra, trigonometry, plane and spherical, theory of equations, the easier parts of analytical geometry, plane and solid, including curvature of curves and surfaces, differential and integral calculus, easier parts of differential equations, statics, including elementary propositions on attractions and potentials; hydrostatics, dynamics of a particle, easier parts of rigid dynamics, easier parts of optics and spherical astronomy. Those who pass this second part will be arranged as wranglers, senior optimes, and junior optimes in order of merit. Both the examinations in Parts I. and II. will take place in June. The examination in Part III. will be held in January, and be open only to those who are classed as wranglers. It will last three days. On the tenth day after the end of the examination in Part III. the moderators and examiners, taking into account the examination in that part only, shall publish in three divisions, each division arranged alphabetically, those examined and approved. The moderators and examiners may place in the first division any candidate who has shown eminent proficiency in any one group of the subjects in Schedule III.

THE *University College of Wales Magazine*, the first number of which lies before us, is a neat little publication of fifty-two pages, doing credit to the Oswestry press from which it issues, as well as to the enterprise of the Aberystwith Institution, and the ability of its members. We do not suppose its promoters expect a large general circulation, though there is no reason why the magazine might not be so conducted as to meet with considerable favour in the principality. Curiously enough, the first paper after the introduction is on Persian literature, while one on Welsh literature occupies the sixth place. There is a paper on Cambria at Paris, showing what a good appearance she made at the recent exhibition; a Welsh story, an Oxford letter, college news, &c. We wish the magazine success; and it might do good service by devoting itself to research in various directions in regard to Wales. We should like to see the science professors in this college fill up some of its pages.

THE First Annual Report of the Dulwich College Science Society is, on the whole, satisfactory; the appended lists, forming the bulk of the volume, show that the Society has several diligent collectors, and we hope it will continue to do genuine work and nourish in the scho l a lasting love of real science.

PROF. H. G. SEELEY completed on Friday at the College for Men and Women, 29, Queen Square, Bloomsbury, a course of six lectures on some of the principal forms of extinct animals which resemble reptiles and birds, and have no representatives now living. The subjects have been as follows:—Lecture I.—On the Geological Distribution of Fossil Reptiles and Birds; and concerning points in which Extinct Reptiles differ from those which now inhabit the Earth. Lecture II.—The Ichthyosaurians and Animals of the Open Ocean. Lecture III.—The Plesiosaurians and Animals of the Sea Shore. Lecture IV.—The Dinosaurians and Allied Types of Land Animals. Lecture V.—The Ornithosaurians and other Flying Types of Life. Lecture VI.—The Classification of Reptiles and Allied Fossil Animals, as illustrating some Aspects of the Doctrine of Evolution.

PROF. WURTZ was charged some time since by the French Minister of Public Instruction, to make an inquiry into the organisation of the laboratories and practical instruction given in the several universities of Germany and Austro-Hungary. Prof. Wurtz accordingly made several journeys to the great seats of learning in these two countries, and the *Journal Officiel* of last Saturday publishes at full length his report. Prof. Wurtz insists strongly on the danger of creating large establishments, where students are taught something of everything, and on the necessity of creating special foci for every large section of experimental science. He shows the advantage of special institutes, and insists upon the organisation of chemical, physical, physiological, anatomical, and pathological institutions such as flourish on the other side of the Rhine, and may be established in Alsace-Lorraine. He ends his report by describing the Munich Hygienic Institute.

THE French budget of Public Instruction has been voted *au pas acceleré*. The resolutions proposed by the Commission were voted without any material alterations. The estimates reach about 2,000,000*l*.

The University of Bern celebrated, on November 15, the forty-fourth anniversary of its foundation. It numbers among its students, about twenty ladies, mostly Russians, who study medicine.

ACCORDING to a new law, all children who finish their education in any school of the Canton of Bern are submitted to an examination. This year 4,610 boys and 4,446 girls were examined (total population of the Canton 537,000), and the results proved unsatisfactory. The Canton continues to occupy the eighteenth and twenty-first places in the Cantons of the Swiss confederation.

A WEALTHY Serbian, Ilija Milosavljewitch Kolaraz, who died a month ago at the ripe age of eighty-two, has left the sum of 100,000 ducats for educational purposes, 10,000 ducats for the publishing of valuable works in the Serbian language, and 60,000 ducats for the foundation of a Serbian university at Belgrade, which is to be known as Kolaraz' University.

SCIENTIFIC SERIALS

Journal of Anatomy and Physiology, July, 1878.—Dr. Ogston, of Aberdeen, gives an account of the growth and maintenance of the articular ends of adult bones. He believes that the articular cartilage produces the osseous tissue beneath it, forms the epiphyses, supplies their waste, and maintains them in their proper size and bulk during adult life.—Prof. Cleland describes the brain in cyclopians or one-eyed monsters, including specimens of human kind, dogs, lambs, and pigs. He finds that there is no trace of a retina in the cyclopian eyeball, and that moreover there is an arrest of the development of the first cerebral vesicle.—Dr. Creighton gives an exhaustive account of the formation of the placenta in the guinea-pig, and refers very prominently to its early development in connection with the structure of the ovaries and supra-renal bodies.—Prof. Turner contributes notes on the fœtal membranes of the reindeer, and on the oviducts of the Greenland shark.—Mr. David Newman's paper on the functions of the kidney gives an account of the physical influences which promote secretion, so far as can be demonstrated by experiments with animal membranes and the kidneys of animals recently killed.—Dr. Dodds' historical and critical analysis of our knowledge upon the localisation of the functions of the brain deals with the anatomy of the brain in this number.

October.—Dr. Cunningham, of Edinburgh, gives his deductions on the intrinsic muscles of the mammalian foot, derived from a large number of dissections; and further describes the muscles of the foot of cuscus and thylacine.—Prof. Miall and Mr. Greenwood conclude their valuable memoir on the anatomy of the Indian elephant, dealing with the alimentary canal and

its appendages, and the other abdominal and thoracic viscera.—Dr. Creighton publishes his observations on the supra-renal bodies based on microscopical investigations of these organs when adult and during development, and shows how they present many features of analogy to the ovaries.—Prof. Humphry gives his reasons for dissent from Dr. Ogston's views on the important share taken by articular cartilage in the growth of bone, as expressed in the July number of the *Journal*.—Prof. Turner describes the placentation of the hog-deer (*Cervus porcinus*).—Dr. Urban Pritchard supplements his previous accounts of the development of the organ of Corti in the internal ear.—Dr. T. B. Henderson, of Glasgow, describes the physiological effects of the inhalation of phosphuretted hydrogen.

Journal de Physique, October.—In this number Prof. Dufet studies the variation of the indices of refraction in mixtures of isomorphous salts, arriving at the experimental law that the differences between the indices of a mixture of two such salts and those of the component salts are in inverse ratio of the numbers of equivalents of the two salts forming the mixture; in other terms the curve which has for ordinates the indices and for abscissæ the equivalents, is a straight line. This law is regarded as a consequence of Gladstone's, on the constancy of specific *refractive energy* in mixtures.—M. Terquem describes an improved way of realising Plateau's liquid laminar systems, giving larger systems with less liquid. Instead of using pieces all rigid, he uses a combination of rigid pieces with flexible threads (silk), *e.g.*, two horizontal rods joined together at the ends with such threads or two rings joined with threads. Many instructive effects are thus had. The liquid used is a solution of soap and sugar, prepared in a special way.—M. Bouty contributes a mathematical paper on the number of elements necessary for determining the exterior effect of an optical system, and M. Bichat gives a new method of measuring the velocity of sound.

SOCIETIES AND ACADEMIES

London

Royal Society, November 21.—"On Repulsion resulting from Radiation." Part VI., by William Crookes, F.R.S., V.P.C.S.

In this part, with which the research closes, the author first examines the action of thin mica screens fixed on the fly of an ordinary radiometer, in modifying the movements. It is found that when a disk of thin clear mica is attached 1 millim. in front of the blacked side of the vanes of an ordinary radiometer, the fly moves negatively, the black side approaching instead of retreating from the light. When a thin mica disk is fixed on each side of the vanes of a radiometer, the result is an almost total loss of sensitiveness.

In order to examine the action of screens still further an instrument is described having the screens movable, and working on a pivot independent of the one carrying the fly, so that the screens can move freely and come close either to the black or to the white surfaces of the disks. By gentle tapping the screens can be brought within 2 millims. of the black surfaces. A candle is now brought near, shaded so that the light has to pass through one of the clear disks and fall on the black surface. The black side immediately retreats, the clear disk remaining stationary for a moment, and then approaching the light. If the candle is allowed to shine on the plain side of the black disk, no immediate movement takes place. Very soon, however, both disks move in the same direction away from the candle, the speed of the clear disk gradually increasing over that of the blacked disk.

Instead of allowing the clear screens to freely move on a pivot, an instrument was made in which the screens could be fixed beforehand in any desired position in respect to the blacked disk. It was then found that with the screens close to the blacked sides of the vanes the fly rotates very slowly in the negative direction, stopping altogether when the candle is moved five or six inches off. With the screens 1 millim. from the black surface the direction is negative, and the speed at its maximum. When the screens and disks are 7 millims. apart a position of neutrality is attained, no movement taking place. When the distance is further increased, positive rotation commences, which gets stronger as the screens approach the bright sides of the disks, where the positive rotation is at its maximum. The author adduces reasons for considering that the negative rotations here observed are caused by the warming up of the black surface by radiation falling direct on it, through the clear mica screen, and the deflection backwards of the lines of molecular pressure thereby generated.

The action of these radiometers being complicated, owing to the surfaces of the vanes being different in absorptive power, another instrument was made in which the vanes were of polished aluminium, perfectly flat and symmetrical with the bulb. The screens were of clear mica movable in respect to the vanes, and at right angles to their surface. When exposed to the light of a candle it was found that with the screens brought up close to the disks, the rotation was as if the unscreened side were repelled; at an intermediate position there was neutrality. Explanations are given of these movements, but without the illustrative cuts they would be unintelligible.

Experiments on radiometers having movable screens interposed between the vanes and the bulb are next given, and these are followed by a long series of experiments on the influence of movable screens on radiometers with cup-shaped metallic vanes, the screens being varied in shape and position in respect to the plane of rotation, as well as in respect to the distance from the vanes.

A similar series is given with metallic cylinders as vanes, and from the behaviour of the latter kind of radiometer an explanation is given of the various movements previously obtained. It is found that when the screen touches the convex surface of the vanes the rotation under the influence of light is always positive. It commences at a low exhaustion, increases in speed till the rarefaction is so high that an ordinary radiometer would begin to lose sensitiveness, and afterwards remains at about the same speed up to the highest rarefaction yet obtained. At any rarefaction after 87 M (millionths of an atmosphere) there is a neutral position for the screen. When it is on the concave side of this neutral position the direction of rotation is positive, and when on the convex side of the neutral position it is negative; the speed of rotation is greater as the vanes are further removed from this neutral position on either side. The position of this neutral point varies with the degree of exhaustion; thus at 12 M the screens must be 3 millims. from the convex side; at ·18 M they must be 13 millims. from the convex side. The higher the exhaustion the greater the distance which must separate the convex side of the hemi-cylinders and the screens.

The author gives explanations of these phenomena based on the following already ascertained facts:—When thin aluminium vanes are exposed to light the metal rises in temperature and becomes equally warm throughout, and a layer of molecular pressure is generated on its surface. The thickness of this layer of pressure, or the length of the lines of force of repulsion varies with the degree of exhaustion, being longer as the exhaustion increases. The lines of force appear to radiate from the metal in a direction normal to its surface. The force of repulsion is also greater the closer the repelled body is to the generating or driving surface, and the force diminishes rapidly as the distance increases, according to a law which does not appear to be that of "inverse squares." Diagrams are given illustrating the author's explanation based on the above data.

An apparatus is next described not differing in principle from the last, but having, in addition to the aluminium hemi-cylinder and movable mica screen, a small rotating fly made of clear mica, mounted in such a way that it could be fixed by means of an exterior magnet in any desired position inside the bulb. The screen was also capable of adjustment by means of another magnet; the aluminium hemi-cylinder in this apparatus being fixed immovably. The adjustible indicator being very small in diameter in comparison to the other parts of the apparatus, and, being easily placed in any part of the bulb, was expected to afford information as to the intensity and direction of the lines of pressure when a candle was brought near the bulb. Experiments have been tried, *a*, with the screen in different positions in respect to the hemi-cylinder; *b*, with the indicator in different parts of the bulb; *c*, with the candle at different distances from the hemi-cylinder on one side or the other; *d*, with the degree of exhaustion varying between wide limits. It would be impossible to give an intelligible abstract of the results obtained with this apparatus without numerous diagrams It may, however, be briefly stated that they entirely corroborate the theories formed from a study of the behaviour of the instruments previously described.

The next part of the paper treats of the action of heat employed inside the radiometer. In a previous paper the author

showed that phenomena feeble and contradictory when caused by radiation external to the bulb, became vigorous and uniform when the radiation was applied internally by the agency of an electrically-heated wire. It was hoped that some of the more obscure phenomena shown by the deep cups with movable screens in front (referred to above) might be intensified if set in action by a hot wire. Several inds of apparatus and experiments with them are described, but the results are too complicated to be given in abstract. One experiment proves that the direction of pressure is not wholly normal to the surface on which it is generated, but that some of it is tangential.

The author then describes the turbine radiometer, early specimens of which were exhibited before the Royal Society on April 5, 1876. In the ordinary form of radiometer the number of disks constituting the fly is limited to six or eight, a greater number causing interference one with the other and obstruction of the incident light. In the turbine form of fly there is no such difficulty, the number of vanes may be considerably increased without overcrowding, and with corresponding advantage. In the earlier turbine radiometers the flies were made of mica blacked on both sides, and inclined at an angle like the sails of a windmill, instead of being in a vertical plane. This form of instrument is not sensitive to horizontal radiation, but moves readily in one or other direction to a candle held above or below. A vertical light falling on the fly gives the strongest action, but rotation takes place, whatever be the incident angle, provided the light is caught by one surface more than by the other. Ether dropped on the top of the bulb to chill it causes rapid negative rotation. If the turbine radiometer is floated in a vessel of ice-cold water, and the upper portion exposed to the air of a warm room, it rotates rapidly in the positive direction, acting as a heat engine, and continuing so to act until the rotating fly has equalised the temperature of the upper and lower portions of the bulb. By reversing the circle of operations—by floating the turbine radiometer in hot water and cooling the upper portion of the bulb—the fly instantly rotates in the negative direction.

After describing experiments in which the same fly was made to rotate first in a large bulb and then in a small one at the same degree of exhaustion, the author proceeds to discuss the influence exerted by the inner side of the glass case of the radiometer as a reacting surface. A flat metal band was put equatorially inside a radiometer, and lamp-blacked, so that the molecular pressure generated under the influence of light should react between the fly and the black band, instead of between the fly and the glass side of the bulb. It was found that the maximum speed with the band present was 40 revolutions a minute, against 8¼ revolutions when the band was absent.

The rotation of the case of a radiometer, the fly being held immovable by magnetism, is next described. A preliminary note on this subject having already appeared in the *Proceedings*,[1] it need not be again described in detail. Many different forms of instrument for effecting this rotation are described, and their mode of action explained.

The reacting inner surface of the envelope being thus proved to be essential to the rotation of the fly, other instruments were made in which this necessary reaction is obtained in a more direct manner. In one, the radiometer is furnished with a fly carrying four flat aluminium vanes, polished on both sides. Three vertical partitions of thin clear mica are fixed in the bulb, with their planes not passing through the axis of rotation, but inclined to it, thus throwing the obliquity off the fly on to the case, and giving three fixed planes for the reaction to take place against. Candles arranged symmetrically round the bulb make the fly rotate rapidly against the edges of the inclined planes. Breathing gently on the bulb gives negative rotation. A hot glass shade inverted over the instrument causes strong negative rotation, changing to positive on cooling. When the fly is furnished with clear mica or with silver flake mica vanes, the same results are obtained as when aluminium vanes are employed. The principal action is produced by dark heat warming the bulb, screens, and vanes.

The *otheoscope* is the next subject treated on in the paper. This has already been given in abstract,[2] and need not be again referred to. Many different varieties of otheoscope are figured and described.

It was suggested by Prof. Stokes that a disk might be made to revolve on its axis, and the author describes an instrument in which this suggestion is carried out. The disk is horizontal, mounted like the fly of a radiometer, and for lightness' sake is of mica, blacked above. Fixed to the bulb above the disk are four flat pieces of clear mica; each extends from the side of the bulb to near the centre, and ends below in a straight horizontal edge, leaving just space enough for the disk to revolve without risk of scraping. The edge is in a radial direction, and the plane of the plates is inclined about 45° to the horizon in the same direction for them all. Exposed to the light of a candle the rotation is against the edge. By slightly modifying this form the instrument becomes much more sensitive.

[1] *Proc.* Roy. Soc., No. 168, March 30, 1876.
[2] *Proc.* Roy. Soc., No. 180, April 26, 1877.

Whilst experimenting with the otheoscope it was found that, for a given exhaustion, the nearer the reacting surfaces were together the greater was the speed obtained. In the *Proceedings* of the Royal Society for November, 1876,[1] the author described an apparatus by which he was able to measure the thickness of the layer of molecular pressure generated when radiation impinged on a blackened surface inclosed in an atmosphere the rarefaction of which could be varied at will.

It was found that in this apparatus repulsion could be obtained at ordinary atmospheric pressures. Observations are given at normal pressure and at various degrees of rarefaction, with the driving and moving surfaces separated 1, 2, 3, 4, 6, 8, and 12 millims.; and diagrams of the resulting curves are shown when the atmospheric tension and the force of repulsion are used as abscissæ and ordinates. The tables and curves show that the law of increase of the force with the diminution of the distance between the disks does not remain uniform at all rarefactions. At the lowest exhaustions the mean path of the molecules of the attenuated gas is less than 1 millim., as rendered evident by the force of repulsion diminishing rapidly as the distance increases. At exhaustions higher than 9 millims. this condition alters, and as the gauge approaches barometric height the molecular pressure tends to become uniform through considerable distances, the mean path of the molecules now being comparable with the greatest distance separating the surfaces between which they act.

A similar apparatus to the one in which the last experiments were tried was used to measure the action at pressures at and approaching atmospheric. At pressures between atmospheric and 210 millims. the first action is very faint repulsion, immediately followed by strong attraction. The attraction then begins to decline, until, at 15 millims. pressure, it disappears. At the same time the repulsion, which begins to be apparent at 250 millims., increases as the attraction diminishes. The author considers that the attraction is the result of air-currents, caused by the permanent heating of the surface in front of the movable disk.

The paper concludes with experiments undertaken to measure the amount of repulsion, using a horizontal torsion balance,[2] on the principle of Ritchie's, in which the force of repulsion is balanced by the torsion of a fine glass fibre. The *pan* of the balance is a clear mica disk, and a similar disk is fastened to the tube in which the beam oscillates. This fixed disk is lamp-blacked on the upper side, and beneath is a spiral of platinum wire, connected with terminals sealed through the side of the tube. When the spiral is ignited by a constant electric current the blacked mica disk fixed above it becomes heated, and the molecular pressure thereby generated between it and the mica pan causes the latter to rise. The glass thread attached to the beam is thus twisted, and by means of a graduated circle the number of degrees through which the thread has to be turned in order to bring the beam back to equilibrium is noted. This gives a measurement of the pressure exerted, in torsional degrees, and these are converted into grains by ascertaining how many torsional degrees correspond to a known weight. A ray of light reflected from a mirror in the centre of the beam is used as an index, being brought back to zero at each experiment. The author gives in a table, and also shows in the form of a curve, the results obtained with this apparatus, giving the force of molecular pressure in grains weight at exhaustions varying between 2,237 and 0·7 millionths of an atmosphere.

Mathematical Society, November 14.—Lord Rayleigh, F.R.S., in the chair.—The Treasurer's and Secretaries' reports having been read and adopted, Prof. W. G. Adams, F.R.S., consented to act as auditor.—The scrutators declared the following gentlemen elected as the Council for the ensuing session, viz., Mr. C. W. Merrifield, F.R.S., President; Prof. Cayley,

[1] *Proc.* Roy. Soc., No. 175, vol. xxv. p. 310.
[2] For a description of this form of torsion balance, see the author's paper, *Phil. Trans.*, 1876, vol. clxvi. pt. 2, p. 371.

F.R.S., and Lord Rayleigh, F.R.S., Vice-Presidents; Mr. S. Roberts, F.R.S., Treasurer; Messrs. M. Jenkins and R. Tucker, Hon. Secretaries. Other Members: Mr. J. W. L. Glaisher, F.R.S., Mr. H. Hart, Dr. Henrici, F.R.S., Dr. Hirst, F.R.S., Dr. Hopkinson, F.R.S., Mr. A. B. Kempe, Dr. Spottiswoode, F.R.S., Prof. H. J. S. Smith, F.R.S., Mr. H. M. Taylor, and Mr. J. J. Walker.—Mr. Merrifield having taken the chair, Mr. J. D. H. Dickson was elected a Member, and Prof. W. S. Jevons, F.R.S., was proposed for election. The Rev. A. Freeman and Prof. Reinold were admitted into the Society.—The Chairman read a letter from Mr. Warren de la Rue, F.R.S., respecting a memorial to M. Leverrier.—The following communications were made to the Society:—On the instability of jets, by Lord Rayleigh.—On self-strained frames of six joints, by Prof. Crofton, F.R.S. (read by Mr. Hart).—On equivalent statements, iii., by Mr. H. McColl (abstract, read by Mr. Tucker).—The last paper contained a solution of a test problem to show the power of the author's method of elimination; then, an explanation, with illustrations and applications, of another allied method, called the "method of unit and zero substitution;" thirdly, a brief indication of the way in which this algebra of logic may render important service to scientific men in investigating the causes of natural phenomena; and lastly, a brief criticism of Prof. Jevons's method of solving logical problems.

Linnean Society, November 21.—Dr. Gwyn Jeffreys, F.R.S., vice-president, in the chair.—Dr. W. P. Kesteven exhibited, and a short note was read on some specimens of the so-called *Tête anglais* (*Melocactus communis*) from Vieuxfort, St. Lucia. There also was exhibited roots, tendrils, and tubers in different stages of *Vitis gongylodes* and *V. cuspidata*, illustrating the paper immediately thereafter read, viz.: On branch tubers and tendrils of *Vitis gongylodes*, by Mr. R. Irwin Lynch. Subterraneous tubers are by no means rare among plants, *e.g.*, the potato, but in contrast those of *V. gongylodes* present on the stem are aerial, at a height, and on dropping to the ground strike root. Cylindrical, of considerable size, and tenacious of life, they doubtless are a safeguard in propagation of the plant under circumstances prejudicial to the seed. The tendril possesses terminal adhesive disks, and these are formed without the stimulus of contact with any substance, therefore opposed to certain other climbers mentioned by Mr. Chas. Darwin. The aerial roots are of great length, eleven feet and more, they spring from each node, and are of a rich crimson colour in summer, so that they are attractive objects as seen in the Victoria House at Kew.—Report on the Mollusca of the *Challenger* expedition, by the Rev. R. Boog Watson. After introductory remarks, the author describes three genera of the Solenoconchia. Of these *Dentalium* has eighteen species, eleven being new. *Siphodentalium* has seven species, all new to science. Of *Cadulus* two only are already known, nine species and one variety being now recorded for the first time. In all, thirty-six species and four varieties, whereof twenty species were hitherto unknown. Some are of high interest, inasmuch as being remnants of genera now living which have existed since the cretaceous epoch.—The Secretary read the abstract of a paper by Mr. John Miers, on the Symplocaceæ. The author gives credit to Mr. Bentham for the earliest accurate knowledge of the group. The authors of the "Genera Plantarum" recently adopted the example of Prof. A. De Candolle, who regarded the Symplocaceæ as a mere tribe of the Styraceæ. This appears objectionable to Mr. Miers, who, with historical remarks, &c., gives grounds for his adverse opinion. Then follows a synopsis of, to him, eleven recognisable genera, with diagnoses of same, and lists of 125 species.—On the Algæ of Lake Nyassa, by Prof. Dickie, a brief communication, wherein he mentions being indebted to Dr. Laws, of the Livingstonia mission, for the collection. All the genera of the Algæ are known European forms, while the Diatomaceæ, with few exceptions, are likewise widely-diffused species, the only peculiar form being *Epithemia clavata*.—Messrs. Thos. Davidson, F.R.S., and Fred. Jas. Faraday, were elected Fellows of the Society.

Chemical Society, November 21.—R. Warington in the chair.—The following papers were read:—A chemical study of vegetable albinism, by Prof. Church. The author has made numerous analyses of white and green leaves of the same age from the same plant, in order to discover whether any difference in their composition could be detected. The leaves were gathered from the maple, the holly, the ivy, and three exotic plants. White leaves contain more water than corresponding green leaves, whilst the ash of white leaves contains more potash and phosphoric acid, but less lime, especially less oxalate and carbonate of calcium. Nearly sixty per cent. of nitrogen in the white leaves is non-albumenoid, while the green leaves contain thirty per cent. of nitrogen in that state. The author has also analysed a vegetable parasite, the dodder, and its host, the red clover; he finds that the white leaves resemble in composition the parasite, while the host represents the green leaves. The white leaf is therefore, in a sense, a parasite on the green leaf, and owes its existence to its connection with the normal portion of the plant.—Relation between the melting-points of the elements and their coefficients of expansion, by Dr. Carnelly. The author finds that, of thirty-one elements, twenty-six show that the coefficient of expansion increases as the melting-point diminishes; the five exceptions are arsenic, antimony, bismuth, tellurium, and tin.—A preliminary notice on a hydride of boron, by F. Jones. The author succeeded in preparing a grey friable mass of magnesium boride by strongly heating a mixture of magnesium dust and boron trioxide. On heating this mass with hydrochloric acid, a colourless gas was evolved, spontaneously inflammable, burning with a green flame, and of disagreeable odour.

Zoological Society, November 19.—Mr. A. Grote, vice-president, in the chair.—Mr. Sclater exhibited and made remarks on an adult specimen, in full plumage, of the black-throated stonechat (*Saxicola stapazina*), which had been obtained in Lancashire, and had been sent for exhibition by Mr. R. Davenport. The species had not been previously recorded as occurring in the British Isles, and was an interesting addition to the list of "Accidental Visitors."—The Secretary read two letters he had received from Dr. A. B. Meyer and Mr. A. D. Bartlett in reference to the communication read at the last meeting from Mr. Everett respecting the supposed existence of the anoa (*Anoa depressicornis*) in the Philippines.—Prof. Owen, C.B., read a memoir on the relative positions to their constructors of the chambered shells of cephalopods.—Sir Victor Brooke, Bart., read a paper on the classification of the Cervidæ, and gave a synoptical list of the existing species of this family.—A second paper by Sir V. Brooke contained the description of a new species of gazelle from Eastern Africa, which the author proposed to name *Gazella walleri*, after its discoverer, Mr. Gerald Waller.—Prof. A. H. Garrod, F.R.S., read a paper on the anatomy of *Indicator major*, and showed that, as regards its soft parts, as in its osteology, *Indicator* is not related to the cuckoos, but to the barbets and toucans.—A communication was read from the Marquis of Tweeddale, F.R.S., containing the eleventh of his contributions to the ornithology of the Philippines. The present paper gave an account of the collection made by Mr. A. H. Everett at Zamboanga, in the Island of Mindando. Ninety-eight species were obtained in this locality by Mr. Everett, of which eleven were new to the Philippine fauna and six were new to science.—Mr. E. R. Alston read some notes supplementary to his paper on the squirrels of the neotropical region.

Entomological Society, November 6.—Mr. H. W. Bates, F.L.S., F.Z.S., president, in the chair.—Mr. Waterhouse exhibited a specimen of *Chauliognathus excellens* (*Telephoridæ*), a new beetle from New Granada.—Mr. H. T. Stainton exhibited a new horn-feeding *Tinea* (*T. orientalis*), which had been reared by Mr. Simmons, of Poplar.—The Rev. H. L. Gorham exhibited some rare British beetles, taken in the neighbourhood of Horsham, Sussex.—Mr. Goss exhibited specimens of a rare dragon fly (*Cordulia curtisi*) from Christchurch, Hampshire.—Mr. Meldola exhibited a male specimen of the moth *Erebus odorus*, from Jamaica, possessing large tufts or brushes on the hind leg, which were considered as probably scent-secreting organs.—Prof. Wood Mason exhibited drawings and made remarks on the flower simulating *Mantidæ*.—Mrs. Randolph Clay exhibited a living specimen of a beetle (*Zopherus bremëi*), from Yucatan, worn as an ornament.—Sir Sydney Saunders exhibited specimens of *Blastophaga psenes* (Linn.), employed in the process of cuprification, received from Mr. J. Lichtenstein, of Montpellier.—Also specimens of *Sycophaga crassipes*, West., from the sycamore figs of Egypt, together with certain apterous associates.—The Secretary read a communication from the Board of Trade with reference to the damage done to the corn crops in the neighbourhood of Mariapol by swarms of the beetle *Anisoplia Austriaca*.—A sub-committee was appointed to draw up a report on the same.—Miss E. A. Ormerod read a paper on *Psila rosæ*, the well-known insect producing the so-called "rust" in carrot crops.

She advocated the use of a phenol preparation for the destruction of this pest.—Mr. C. O. Waterhouse read a paper containing descriptions of new *Telephoridæ* from Central and South America.—Sir Sydney Saunders communicated a paper on the habits and affinities of *Sycophaga* and *Apocrypta* from the sycamore figs of Egypt.—Mr. Distant communicated descriptions of new species of Hemiptera-Homoptera.

Geological Society, November 6.—Henry Clifton Sorby, F.R.S., president, in the chair.—Arthur Goodger, Rev. Walter Howchin, Lieut.-Col. C. A. McMahon, Oswald Milton Prouse, and M. G. Stuart, were elected Fellows of the Society.—The following communications were read:—On the range of the mammoth in space and time, by Prof. W. Boyd Dawkins, F.R.S. The author expressed his opinion that the result of the evidence collected since the death of Dr. Falconer has been to establish the view of that palæontologist as to the mammoth having appeared in Britain before the glacial epoch. The evidence as to the occurrence of the mammoth in the south of England was first examined. The remains found beneath the bed of erratics near Pagham belonged, not to *Elephas primigenius*, but to *E. antiquus*. But in 1858 remains belonging to the former were found by Prof. Prestwich under boulder-clay in Hertfordshire. In Scotland remains of *E. primigenius* have been found under boulder-clay, but whether under the oldest boulder-clay is uncertain. In 1878 a portion of a molar was brought up from a depth of sixty-five feet near Northwich. It was in a sand beneath boulder-clay, which the author considered to be undoubtedly the older boulder-clay. The author now assents to Dr. Falconer's opinion (which he formerly doubted) that *E. primigenius* was a member of the Cromer forest-bed fauna. It is also clear that it was living in the southern and central parts of England in post-glacial times. It has not been found north of Yorkshire on the east and Holyhead on the west, probably because Scotland and north-west England were long occupied by glaciers. Its remains have been found on the continent as far south as Naples and as far north as Hamburg, but not in Scandinavia. Its remains, as is well known, abound in Siberia, and it ranged over North America from Eschscholtz Bay to the Isthmus of Darien, *E. columbi*, *E. americanus*, and *E. Jacksoni* being only varieties. The author then discussed the relations of *E. primigenius* to *E. columbi*, *E. armeniacus*, and *E. indicus*, and came to the conclusion that it is the ancestor of the last.—The mammoth in Siberia, by H. H. Howorth, F.S.A. Communicated by J. Evans, LL.D., F.R.S. The author discussed the theories which account for their presence:—1. That the animals lived much further south, and were carried down by rivers to where they now lie; 2. That they lived on the spot. As there are physical difficulties in the way of the transport theory, as the mammoth was covered with dense hair and fed on plants growing on the spot, and as the remains are not confined to the vicinity of rivers, it is probable that the second view is the correct one. It seems probable that the climate of Siberia has become more severe. The author considered the cause of the mammoth's extinction. This he held to have been sudden. The remains must have been preserved after death. He therefore maintains that they were destroyed by a flood due to some sudden convulsion which also changed the climate.—On the association of dwarf crocodiles *Nannosuchus* and *Theriosuchus pusillus*, *e.g.*) with the diminutive mammals of the Purbeck series, by Prof. R. Owen, C.B., F.R.S. The author noticed an objection which had been raised to his view of the origin of the differences between the mesozoic and neozoic crocodiles by the adaptation of the latter to the destruction by drowning of large mammalia (*Q. J. G. S.*, xxxiv. p. 422), namely, that mammals were coexistent with the mesozoic forms, and remarked that from their small size they would hardly constitute a suitable prey for the crocodiles to which he then specially referred, but would be more likely to perform the same part as the ichneumons of the present day, which check the increase of crocodiles by destroying their eggs and newly-hatched young. He stated, however, that in waste slabs of "feather-bed" marl which accompanied the Becklesian Purbeck Collection to the British Museum, the remains of small crocodiles were detected in considerable abundance; and he gave a description of these, and especially of one which he named *Theriosuchus pusillus*. This reptile, which is estimated to have been about eighteen inches long, had scutes presenting the "peg and groove" character of those of *Goniopholis*, with which genus it further agreed by having the antorbital part of the skull of the broad-faced alligator type. In the dentition it resembled the triassic theriodonts more than any other crocodiles. The vertebræ are amphiplatyan. In conclusion, the author indicated the conditions which have to be fulfilled in the case of recent crocodiles to enable them to drown a large mammal without inconvenience to themselves, and showed that these conditions were realised also in the neozoic forms, whilst there was no reason to suppose that any mesozoic crocodiles possessed the adaptations in question.

Anthropological Institute, November 12.—Mr. John Evans, D.C.L., LL.D., F.R.S., president, in the chair.—The following new Members were announced:—Mr. M. J. Gabriel, and Mr. George H. Radford.—Mr. Robert Cust read a report on anthropological proceedings at the Oriental Congress, in which he gave a digest of all the papers and discussions at that Congress which appertained to the science of anthropology.—Mr. Park Harrison read a paper on some characters which are still in use as tattoo-marks by the Motu, a people located in the South-Eastern Peninsula of New Guinea, and described by the Rev. Dr. Turner as a superior race to the Papuans, from whom they differ both in colour and customs. About half of the more distinctive forms tattooed on a Motu girl, carefully copied by Dr. Turner, correspond with letters in the Asoka inscriptions in India, which are believed to be allied to Phœnician, whilst several others resemble letters admittedly derived from the same stock, but independently acquired. The marks are mostly arranged in groups of three; on the right arm, however, nine or ten are apparently connected by a line running above them all. The characters are twenty-three in number, and are formed of straight lines in the following combinations; viz., five of 2 lines, nine of 3 lines, five of 4 lines, and three of 5 lines, much in the same proportion as in the Rejang and Lampong alphabets of Sumatra, the letters of the former of which have been shown to be identical with Phœnician characters *reversed*. Archaic forms of letters have also been met with in several islands of the Indian Archipelago and Melanesia, but are now without meaning. The Motu characters are used simply for ornament or as charms. As an example of the use of letters for tattoo-marks, the case of the Austrian subject was cited, who, having been taken prisoners in Burmah, a few years ago, was there tattooed with letters and other patterns. Besides the characters on the Motu girl, there were various pictures, or hieroglyphics, consisting of eyes and eyebrows, a lunar crescent, and other forms.

Meteorological Society, November 20.—Mr. C. Greaves, F.G.S., president, in the chair.—Rev. T. L. Almond, Rev. T. C. Beasley, F. T. Bircham, H. F. Blanford, G. Chatterton, E. Easton, W. L. Fox, G. F. Lyster, Lieut.-Col. W. Stuart, R. Tennent, and H. Yool were elected Fellows of the Society.—The following papers were read:—Report on the phenological observations for 1878, by the Rev. T. A. Preston, M.A.—Up-bank thaws, by the Rev. Fenwick W. Stow, M.A.—Comparison of thermometric observations made on board ship, by Capt. H. Toynbee, F.R.A.S.

PARIS

Academy of Sciences, November 11.—M. Fizeau in the chair.—M. Loewy presented a memoir by M. Stephan and himself, on determination of the two differences of longitude, Paris-Marseilles and Algiers-Marseilles. He remarked, on the difference of velocity in transmission of signals through air and under water, that this velocity was found about 36,000 kilom. per second in the former case and 4,000 kilom. in the latter, numbers agreeing closely with those got lately by Dr. Albrecht, in Prussia, from shorter lines.—On the vision of colours, &c., second extract from work by M. Chevreul.—On the dilatation of heated bodies and the pressures they exercise, by M. de Saint Venant.—On the energy of a body and its specific heat, by M. Clausius.—Report on a memoir of M. Popoff, entitled, "New Researches relative to Expression of the Conditions of Motion of Water in Sewers." This shows the necessity of new formulæ, involving either change of known numerical coefficients or consideration of the movement as being generally varied. Several problems are enunciated as needing solution.—On measurement of the magnifying power in optical instruments, by M. Govi. It is inexact to say such and such a lens or microscope magnifies a certain number of times the image of objects, while it is not added at what distance the image must be for this magnification to take place. The distance of distinct vision is variable.—On the possibility of obtaining, with protoxide of nitrogen, an insensibility of long duration, and on the harmlessness of this anæsthetic, by M.

Bert. He recommends putting patients in an apparatus with the pressure raised to two atmospheres, and making them breathe a mixture of 50 per cent. protoxide of nitrogen and 50 per cent. air; thus long anæsthesia is had, while the normal quantity of oxygen is kept up in the blood.—Observations on M. Levy's memoir on a universal law relating to the dilatation of bodies, by M. Massieu.—On the transformation of linear forms of prime numbers into quadratic forms, by M. Oltramare.—Artificial crystallisation of orthose, by M. Meunier. The author obtained this (which MM. Fouqué and Levy are now seeking to effect) some years ago, by devitrification of the vitreous masses called retinites.—New process for application of galvanoplasty to conservation of nervous centres, by M. Oré. A hardened brain is dipped in fused gutta percha, and the gutta percha, on hardening, is divided and separated, forming a mould; this is lined with black lead and put in a nickelising bath; thus a hollow piece is had faithfully reproducing the brain.—Resistance of some wild types of American vines to phylloxera, by M. Millardet.—On the reduction of certain differential equations of the first order to linear form with reference to derivatives of the unknown function, by M. Halphen.—On the form of integrals of differential equations in the neighbourhood of certain critical points, by M. Picard.—On the theory of machines of the Gramme order, by M. Breguet. To obtain the best possible effect from a system formed by a movable circuit rotating in a magnetic field (1) if the motion is caused by a current of foreign source, the diameter of the points of contact should be displaced in the direction opposite to the rotation, and through a greater angle the greater the intensity of the current and the weaker the magnetic field; (2) if the motion has to generate a continuous current in the apparatus the same diameter should be displaced in the direction of the rotation.—Chemical researches on tungstates of earthy and metallic sesquioxides, by M. Lefort.—Analysis of different metallic fragments from the Peruvian burying-places of Ancon, near Lima, by M. Terreil. This reveals the presence of brass in these tombs belonging to the sixteenth century.—Synthesis of uric derivatives of the alloxane series, by M. Grimaux.—On some causes of inversion of cane sugar, and on the consecutive alterations of the glucoses formed, by M. Durin. The causes referred to are heat, water, and time (without pre-existent glucose), the phenomenon being purely chemical.—On the hatching of bees, by M. Girard.—Specific determination of fossil or ancient bones of Bovides, by M. Sanson. The bones of Bovides found in beds before the present geological epoch belong to the groups of bisons and bulls: the first, all to one species, now living (*B. americanus*), the second to four living species (specified).—On the presence of alcoholic ferment in air, by M. Miquel. Sterilised must exposed among the vineyards of the south of France always ferments in a few days; this is attributed to conveyance of wine-yeast by insects. He shows that the air really transports yeast. In the Montsouris Park, Paris, not a single case of spontaneous alcoholic fermentation was met with.—Organisation of *Hydrocrosis arsenicus*, Bret., by M. Marchand.

November 18.—M. Fizeau in the chair.—The following papers were read:—Meridian observations of small plants at the Greenwich and Paris Observatories, during the third quarter of 1878, communicated by M. Mouchez.—On a fresh discovery of Silurian terestrial plants in the slaty schists of Angers, by M. Crié; note by M. de Saporta. This is the frond of a fern resembling most nearly *Cardiopteris polymorpha*, Gœpp., which characterises the carboniferous limestone of Silesia; but it has also special features. (A figure is given.)—Means of measuring the manometric value of the pressure of the blood in man, by M. Marey. This consists in producing on a part of the body surface a known counter-pressure with water, capable of overcoming the blood-pressure in the vessels. The simple immersion of a finger in a suitable apparatus suffices; it has shown that in some adynamic fevers the blood pressure may fall to 3 ctm., while in interstitial nephritis it may rise above 20 ctm.—New remarks on M. Levy's communication, on a universal law relating to dilatation of bodies, by Prof. Boltzmann.—Observations on MM. Gruey and Hirn's notes regarding a gyroscopic apparatus, by M. Sire.—On an alterating gyroscopic tourniquet, by M. Gruey.—On a new system of electric lamp, by M. Werdermann.—Artificial reproduction of felspars and of a complex volcanic rock (pyroxenic labradorite) by the method of igneous fusion, and prolonged maintenance at a temperature near fusion, by MM. Fouqué and Levy.—Migration of pucerons of galls of lentiscus to the roots of Gramineæ, by M. Lichtenstein.—M. Oder presented (through M. du Moncel) an electrophone, with which words and notes can be heard 5 m. off. On one end of a sort of drum is fixed a diaphragm of parchment paper, having at the centre six small bars of white iron, fixed circularly, on which act six very small horseshoe electro-magnets connected together and actuated by a carbon microphone. The strong effects are attributed to the smallness of the magnets, giving more rapid magnetisation or demagnetisation.—Intra-Mercurial planets observed during the solar eclipse of July 29. Letter from Mr. Watson. A reply to questions.—On the development of surfaces whose linear element is expressible by a homogeneous function, by M. Levy.—Note on the determination of imaginary roots of algebraic equations, by M. Farkas.—Action of hydracids on sulphate of mercury; action of sulphuric acid on the haloid salts of this metal, by M. Debray. Sulphate of mercury gently heated in hydrochloric gas absorbs it with liberation of heat, and yields a matter fusible and volatile without decomposition, condensing in fine white needles; it has the formula $HgO,SO_3 + HCl$. It may be had directly by union of mercuric chloride and monohydrated sulphuric acid.—Peculiar action of platinum wire on hydrocarbons; modification of the grisoumeter, by M. Coquillion. Bicarbide of hydrogen mixed with air is more detonant than protocarbide; palladium gives a less detonation than platinum; and these two metals can equally burn at red-white small quantities of gas. Thus platinum may be substituted for palladium where there is no fear of detonations.—On the alkalinity of carbonates and silicates of magnesia, free, mixed, and combined, by M. Pichard.—Action of the cervical sympathetic on the pressure and velocity of the blood, by MM. Dastre and Morat. An unforeseen result is that the initial constriction on stimulation of the nerve is always followed by a dilatation greater than that which follows section of the nerve.—On the toxical power of the extract of seeds of hemlock, by MM. Bochefontaine and Mourrut. The common extract obtained from the whole plant is often almost without action; not so extract from the dry seeds; it is in them the active principle specially resides.—On a disease of lettuce (*Peronospora gangliiformis*, Berk.), by M. Cornu.—On the morphology of dicotyledonous stems, by M. Guinier. He applies the graphic method. *Inter alia*, at heights under 1,400 metres, stems bulge out about the middle; as you go higher, the swelling disappears, and about 1,700 m. height, it is replaced by a concavity. From the leafy head of trees may be deduced the form of the stem.—Observations on the orography of the chain of the Pyrenees, by . Schrader.

BOTANICAL CHEMISTRY

The Organic Constituents of Plants and Vegetable Substances and their Chemical Analysis. By Dr. G. C. Wittstein. Authorised Translation from the German Original, Enlarged with numerous Additions, by Baron Ferd. von Mueller, F.R.S. (Melbourne: McCarron, Bird and Co., 1878.)

MANY who have been interested in botanical studies may have been struck with the varied nature and great number of chemical substances which are extracted from plants and which in many cases impart to the flowers their special and characteristic brilliant colours. Up to the present time we have had in English no work which has devoted itself specially to the systematic description of the nature and preparation of such substances; and the literature in connection with the subject, which is by no means meagre, with accounts of investigations in chemico-botanical research must be sought for in journals generally devoted to purely chemical matter, and consequently less likely to attract the attention or be available for the use of the more general reader.

With regard to other countries, however, this has not been the case, as we find a considerable portion of the work of Berzelius devoted to a consideration of the bodies found in plants, and the "Anleitung zur Analyse von Pflanzen und Pflanzentheilen" of Rochleder has long been known both in Germany and elsewhere as affording a good collection of the results of investigations in vegetable chemistry up to the date of its publication about the year 1858.

During the last year, however, Baron Ferd. von Mueller has brought forward a translation of Dr. G. Wittstein's "Anleitung zur chemischen Analyse von Pflanzentheilen auf ihre organischen Bestandtheile," published in 1868, the value of which he has found in his own researches, and which he has for some time wished to render available for English readers.

The present edition consists of two parts, each divided into three divisions, which form as it were the chapters. In the first part the author has placed the consideration of the proximate constituents of plants and vegetable substances as far as hitherto known, together with their properties and mode of extraction. His first intention in the arrangement of this part, which is naturally the largest portion of the work, was to adopt as far as possible a systematic classification. From the imperfect state of knowledge, however, as to the exact constitution of the bodies, and from the fact also that some of the better known substances possess properties which might cause them to appear in several groups if a classification depending on natural properties was taken, he has finally adopted an alphabetical order and has thus formed a dictionary of so-called phytochemical substances.

In the consideration of the individual substances Baron von Mueller has evidently confined himself almost entirely to their preparation from natural sources, and we have therefore no description of the very interesting and remarkable synthetical methods which are now employed for the production of certain of these bodies. This may of course have been beyond the limit originally intended by the present editor, but we should hope in the event of future editions to have some mention made of the more important recent investigations in this direction. The two latter divisions of the first part are occupied with a synopsis of the plants which yield the bodies previously described and a list of the plants indicated, systematically arranged in their different natural orders. The first of these lists is remarkably good, as it gives not only the names of the plants and those of the substances which they yield, but also the various parts of the plant from which these latter may be extracted. The want of such a list has been felt, and this part of the work might have been extended to rather wider limits; in its present form, however, it will still prove of considerable use. In assigning chemical formulæ to the substances described in the first part of the book the editor has retained the older forms of notation, but has introduced immediately after the alphabetical list of bodies a table containing the molecular weights of the compounds described according to the modern views adopted by chemists; this necessity for two lists concerning the same thing introduces confusion in the mind of the reader, and it would be well therefore in a future edition to dispense altogether with the older forms of molecular weights as they are little used at the present day.

The second part of the work is devoted to the apparatus and reagents necessary for phyto-chemical analysis and to the description of a systematic course embracing the different methods of procedure in conducting such researches. In these analyses one of the most important points is the proper extraction of the various ingredients of the plant; for this purpose solvents such as ether, alcohol, and water are employed. As at first sight it might appear immaterial in what order these solvents are to be used the author points out the importance of employing them in the following order: first ether, then alcohol, and finally water, and by this means preventing such bodies as wax or fat which are completely and entirely dissolved by ether, from passing also into the alcoholic extract in which they are only partially soluble. This also would apply to the extraction of certain of the alkaloids, as in their case partial separation may be carried out in their extraction by the different solvents.

It is to be regretted that the more modern names and atomic weights are not employed in this portion of the work, and also in the description of the preparation of reagents; thus, we find the molecular weight of calcium carbonate given as 625, and that of calcium oxalate as 1025: at the present time the use of such numbers tends greatly to confuse the student.

At the end of the work Baron von Mueller has arranged some useful tables, comprehending the comparison of Centigrade and Fahrenheit thermometric scales, the specific gravity of alcohol of different percentages by weight and by volume, the relation between cubic centimetres and cubic inches, between litres and fluid ounces, and a table of the atomic and molecular weights of the principal elementary bodies.

There can be little doubt that this work supplies a great want in chemical and botanical literature, but there is still room both for the farther elaboration of the matter discussed, and, in certain cases, for some

improvement in the rendering into English of the matter already employed. In the direction of chemico-botanical research there is great room for investigation, and a text-book embracing the knowledge already acquired, and information on points in connection with the chemistry of vegetable physiology, would render such a work of interest not only to the scientific chemist or botanist, but also to the general reader. Baron von Mueller's translation forms an excellent nucleus for such a work, and should a future edition of the book be required, we should hope to find it enlarged in such directions.

J. M. T.

GEOGRAPHICAL ASTRONOMY

Abriss der praktischen Astronomie, vorzüglich in ihrer Anwendung auf geographische Ortsbestimmung. Von Dr. A. Sawitsch, nach der zweiten russischen Original-Ausgabe. Neu herausgegeben von Dr. C. F. W. Peters. (Leipzig, 1879.)

As may be inferred from the title of this work, the astronomical reader will not find it to be a general treatise on the practical branches of the science, but one confined to the theory and uses of instruments, and explanation of methods employed at the present day in the determinations of geographical positions. As such the name of its author, Dr. A. Sawitsch, the well-known Professor of Astronomy in the Imperial University of St. Petersburg, will give the work high recommendation in the estimation of the student. The two volumes of the original edition are now incorporated in one, and such modifications as have been rendered necessary by the introduction of new or improved forms of instruments, and refinements of observation and reduction have been introduced in a great measure by the author himself. In the opening chapter we have explanations of the various methods of reckoning time, and the transformation of one into another; the reduction of mean into apparent places, the calculation of refraction and parallax, and the influence of the earth's compression upon the geocentric co-ordinates of points upon the surface, with remarks upon angular measures in general, and upon the astronomical telescope and its adjustment, the microscopes, verniers, level, &c. In the first section, the author treats of the transit instrument, and enters into the various adjustments to which it is subjected, and also describes in some detail the universal instrument of Piston and Martins, and the errors of division to which instruments for angular measures may be liable. The second section is devoted to the determination of latitude and time by measure of zenith distance, of time from corresponding altitudes, &c. The third section enters more fully into the uses and theory of the transit instrument, and likewise describes Bessel's method for the determination of latitude thereby, supplying practical rules and an example. The next section treats of the determination of azimuth, and of the influence of diurnal aberration on the polar co-ordinates of a star. The fifth section contains a valuable outline of the various methods applicable to the determination of terrestrial longitude, including the telegraphic method, the transportation of chronometers, and longitude by observations of eclipses, especially those of the sun, and by lunar occultations.

The reference to the utility of eclipses for longitude-determination leads to an important chapter on Hansen's method for the calculation of the general circumstances of these phenomena upon the earth's surface, and the methods followed by Dr. Zech, in his researches on the historical eclipses; and, as a numerical example, the formulæ are applied to the computation of the circumstances of the total solar eclipse of August 18, 1887, to which frequent reference has been made in astronomical treatises. The data are founded upon the lunar tables of Hansen and the solar tables of Leverrier. Further, we have a discussion on moon-culminators in their application to longitudes, with notices on the methods of Nicolai and Struve, and a fully-worked-out example. The sixth section relates to the reduction of the longitude, latitude, and azimuth of a place to another, both accurately and approximately, and the determination of the distance of points on the terrestrial spheroid, of which the geographical positions are given. There are two supplementary chapters: the one bearing upon reflection-instruments, and of course entering at length into the use of the sextant; the other treating of interpolation, with special reference to the formulæ of Bessel and Hansen.

In the language in which this work originally appeared it would be almost a sealed book in Western Europe. The excellent translation into a language of which every scientific student should, in these days, possess a knowledge, now placed in our hands by Dr. Peters, will be, without doubt, a welcome addition to his means of instruction on an important branch of practical astronomy.

OUR BOOK SHELF

A Treatise on Dynamics of a Particle, with numerous Examples. By P. G. Tait and the late W. J. Steele. Fourth Edition. (London: Macmillan and Co., 1878.)

THE bibliography of this revised text-book is—a first edition in 1856, 304 pages; a second edition in 1865, 363 pages; a third edition in 1871, 428 pages; and the present edition of 407 pages. There are slight alterations in the disposition and amount of the matter in this edition, caps. x. and xi. of the third are put into cap. ix., caps. v. and vi. are contained in cap. v. of the fourth. The position of some of the exercises has been changed. The main features remain unaltered. The revision has had the advantage of Prof. Greenhill's supervision, who has verified (and corrected where necessary) the Examples and has freely introduced the use of Elliptic Functions. There is no need of any commendation for a text-book so well-known. We are, however, very much disposed to think that had Prof. Tait composed the work at a later date than he did, it would have differed somewhat from its present form and have approximated more closely to the Natural Philosophy brought out under the joint editorship of Sir William Thomson and himself. The author justly complains that "several sections in which some novelties appear have been translated almost *letter* for *letter* and transferred, without the slightest allusion to their source, to the pages of a German work. Several other books have obviously been similarly treated. It is well that this should be known, as the English authors might otherwise come to be supposed to have adopted these passages *simpliciter* from the German."

Familiar Wild Flowers. Figured and Described by F. Edward Hulme, F.L.S., F.S.A. First Series. With Coloured Plates. (Cassell, Petter, and Galpin.)

SCIENTIFIC books are of three kinds: to inform the

scientific world of some fresh discovery or advance—works of research; to offer a digest, for the information of students, of results already attained—text-books; and to attract to the paths of science the outside public—popular works. The pretty and attractive book before us belongs to the last of these categories, and is, we think, well calculated to gain the end in view. It consists of chromo-lithographs of nearly fifty of our better-known native wild flowers, with two or three pages of gossipy talk about each. Of the letter-press not much more can be said than that it is fairly accurate from a botanical point of view, and pleasantly written. The illustrations strike us as unusually good of their kind. They have of course the inherent defects of this mode of illustration, in the absence of half-tones and delicate shades; but the general aspect of the plant is in nearly all cases well and faithfully given, and the drawing is good. The book is a very good one to put in the hands of a child to interest him or her in the wealth of wild flowers which is such a source of delight to all dwellers in the country who have eyes educated to see their beauty.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The Telephone

I HAVE just read an article in NATURE, vol. xviii. p. 698, on the history of the speaking telephone, which contains an erroneous statement of facts which happen to be within my own knowledge; so that, in the interest of a truthful history of this discovery, it is incumbent upon me to make a brief statement in regard to it.

I had the honour to be one of the judges at the International Exhibition at Philadelphia, and of the group to whom was confided the examination of instruments of research and precision. In the performance of my official duty I took part in the experiments which first brought the speaking telephone to the notice of the scientific world. Prof. Bell and Mr. Elisha Gray were both exhibitors at that Exhibition. Mr. Gray's apparatus was conspicuously shown near one of the main aisles, with the exhibit of the Western Electric Company, while Prof. Bell's was in a side room in one of the galleries, as a part of the Massachusetts' educational exhibit. About the middle of June, 1876, Prof. Bell came to Philadelphia to give personal explanations in reference to his apparatus, and before any public exhibition was made he stated to me in detail the character of his inventions. He was working at two independent things, the one the multiple telegraph by means of transmitted musical notes, the other the transmission of articulate speech over long distances. I told him that I was present in May, 1874, at the rooms of Prof. Henry, in the Smithsonian Institution, when Mr. Elisha Gray exhibited to us an apparatus for the electric transmission of musical sounds, and I asked him whether his first invention was similar. He said there was some similarity, although each had worked independently, and that there was a dispute as to the priority of invention. While sanguine as to practical results from his multiple telegraph, his great invention was the speaking telephone, which he believed he had discovered, and in respect to which there was no rival claimant. He said the idea came to him from some of the suggestions in respect to sound vibrations made by Helmholtz, and that he had succeeded, after patient research, in constructing an instrument which would transmit articulate speech. To this invention he desired to direct the attention of the judges.

The experiments with the telephones had to be made when the Exhibition was closed to the public, and the first experiments were made by Sir William Thomson and others on Sunday, June 18 or 25—I do not now remember upon which of these two dates. Their Majesties the Emperor and Empress of Brazil were present at these experiments. Attention was first given to Mr. Gray, and he gave a lengthy account of his experiments, which had resulted in the perfected apparatus which he then exhibited. He gave an explanation of his various instruments in chronological order, and conducted some very entertaining experiments as he proceeded in his discourse. The object which he had in view was to send many messages simultaneously over the same wire by using sending and receiving instruments of different musical notes.

The greater part of the day was given to Mr. Gray, so that insufficient time remained for satisfactory trial of Prof. Bell's apparatus. The judges and the distinguished visitors present did, however, proceed to the Massachusetts gallery, and Prof. Bell explained briefly his two inventions, and some experiments were made with his speaking telephone, enough to excite the curiosity of those present in the highest degree. The results were so at variance with the views hitherto received that it was determined by my distinguished colleague, Sir William Thomson, to make other experiments, in which I took part. These experiments were made two or three days later, in the building known as the Judges' Pavilion, in the evening, after the visitors had left the grounds. Prof. Bell had returned to Boston, and was not present at this trial of his apparatus. It was brought over to the judges' pavilion, at my request, by Mr. Hubbard, one of the officers in charge of the Massachusetts exhibit, and the experiments were made by Sir William Thomson and myself. Every precaution was taken to make an impartial test. I was at the transmitting instrument which was placed out of doors at a distant part of the building, and Sir William Thomson was at the receiving instrument in a distant room in the building. After some experiments to find the pitch of voice which would suit the vibrating membrane then used, I received word by messenger from Sir William that he could then hear distinctly, and accordingly the pitch of voice then used was maintained in the subsequent trials. I held in my hand a copy of the *New York Daily Tribune*, and I began to read to him items from its news summary, and soon the messenger came to tell me that the messages were heard distinctly at the other end. The longest message which I sent was the following from that paper:—"The Americans of London have made arrangements to celebrate the coming Fourth of July," and the messenger brought me back from Sir William Thomson the exact repetition of the message. Thereupon we exchanged places, and I could not only hear distinctly the utterances of my colleague, but I could even distinguish the ictus of his voice. The results convinced both of us that Prof. Bell had made a wonderful discovery, and that its complete development would follow in the near future.

The news of these successful experiments soon circulated freely, and the day following, or possibly two days afterwards, Mr. Gray came to me and inquired whether the reports of our success with Bell's telephone were correct; and upon receiving from me an affirmative reply, he said that it was impossible, that we had been deceived in some way, that the transmission was by actual metallic contact through the wire, and that it was, to use his own words, "nothing more than the old lover's telegraph." In reply I said to him that we had taken every possible precaution against error, that we were both convinced of the reality of Bell's claims, and that Sir William Thomson would report to that effect. He persisted in his statement that the result was impossible, and that we must have been deceived in some way or other.

After having had direct knowledge of Mr. Gray's views at that time, I must confess to some astonishment at his claim now made that he anticipated Mr. Bell in the invention of the speaking telephone. Several months ago I saw an article in *Scribner's Magazine*, by Mr. Prescott, in which, while no direct assertion was made that Mr. Gray was the first inventor, there were illustrations given to show the development of the invention in chronological order, and Mr. Gray's instrument was there given priority. I had it in mind then to write a note to Mr. Prescott upon this subject, but I feared that there might be unpleasant controversies over the patents, and, the claim of Mr. Gray being rather indefinitely stated, I held my peace. But now that the error appears to be taking root, I have felt it to be my duty to make the statements above given. I have before me a letter from Mr. Bell, dated at Boston, Wednesday, June 28, 1876, and directed to me at Philadelphia, in which he gives diagrams showing how we might arrange the apparatus to transmit articulate speech, as he believed, from Boston to Philadelphia, and proposing experiments to that end if the judges should so desire.

In conclusion I ought to state further, that after Sir William Thomson's address at Glasgow had brought the telephone into

notoriety, Mr. Gray, whose instruments had also been called telephones, gave a public exhibition, in Chicago, I think, and in the report of his lecture which I read, he never once alluded to Bell's invention. His discourse was then, as at Philadelphia before the judges, solely in reference to the musical telephone. In fact, the newspapers had to take pains to inform the public that Mr. Gray's invention must not be confounded with Mr. Bell's, to which Sir William Thomson had referred. You will imagine, then, the surprise of the judges who examined these inventions particularly at Philadelphia in 1876, and heard the personal explanations made by the inventors, to be told now that Gray had already invented the speaking telephone, when all his statements then made show directly to the contrary.

Ann Arbor, November 18 JAMES C. WATSON

The Intra-Mercurial Planets

NATURE (vol. xviii. p. 569), in commenting upon my letter published the previous week, regarding the discovery of Vulcan, accused me of being not only "indefinite," but "contradictory." The number containing my letter (p. 539) has, from some unknown cause, not yet reached me, though I am in receipt of four numbers published later.

In the several articles written by me on that subject—to the Chicago Astronomical Society, to the Naval Observatory at Washington, to the Astronomer-Royal, to Admiral Muochez of the Paris Observatory, and to others—I have invariably stated the facts as they occurred under my observation, and as they impressed themselves upon my mind, and have invariably adhered to these statements, viz., that the two stars seen by me were of about the fifth magnitude, about 7′ or 8′ apart, with large red disks, and pointing towards the sun's centre. It is true my letter did contain an error, but not of observation, nor of estimation. In reducing the 8′ of arc (the estimated distance between the stars) to time, I somehow called it 2′, when, in reality, it is but 32s., thus not only changing its position in R.A., but also increasing, in this element, the discordance between Prof. Watson and myself. The detection of this error has changed, to me, the whole aspect of the Vulcan question. I had previously written to Prof. Watson that I could not reconcile his observations with my own either in R.A., or in Dec., but did not tell him what changes were necessary in order that they might harmonise. He gave me his corrected positions, which helped matters considerably, but still his R.A. was too great, and Dec. too little, for, from three estimations, the two stars ranged with the sun's centre. Recently I have been experimenting with α^1 and α^2 Capricorni (two stars which, in respect to distance from each other, resemble those I saw during the eclipse), my object being to test the accuracy of estimations made of the directions towards which two stars will range when hastily brought into the estimated centre of the field of a telescope having a diameter of one and a half degrees. I find that unless the objects are brought exactly to the centre, they do not point to the same place. During totality time was, of course, too precious to waste in being precise in this, and yet I endeavoured to be so, and as at each of the three comparisons they seemed to range with the sun's-centre, I feel convinced that I was not far out in my estimated Dec.

In order to meet Prof. Watson's excessive R.A., I published (contrary, however, to my better judgment), that the distance between the stars was about 8′ instead of 7′ (as previously announced). On the assumption, therefore, that (a) one of the objects was θ Cancri, and (b) that they were 8′ apart, and (c) that the one nearest the sun was the planet, as Watson says, the position of the planet was as follows:—

Washington M. T.	
1878, July 29, 5h. 22 m. R.A., θ Cancri ...	8h. 24m. 40s.
Add 8′ =	32s.
Planet's R.A., Swift ...	8h. 25m. 12s.
,, ,, Watson ...	8h. 27m. 35s.
Difference	2m. 23s.
Dec. Swift	18° 30′
,, Watson	18° 16′
Difference	14′

It will be seen that there is a discrepancy between us of over a half degree of arc in R.A. If we saw the same objects how can we differ so widely? Could I be in error to the amount of 34′ between two stars in the same field? Can two stars be three and one half times the distance of Mizar from Alcor and an observer of experience estimate them at only 7′ or 8′? It will be remembered that I recorded in my note-book at the time the distance as 12′, but knowing how liable I might be to error in the valuation of so large a distance (for though, from practice, I can estimate quite closely double stars whose distances are from 2″ to 20″, I have had no experience in the estimation of those of several minutes separation), I chose to carry it in my mind until I should reach home, when it would be the work of only a few minutes to find two stars of the same apparent distance.

I said to Prof. Hough on our homeward journey, that, from memory, I thought their distance was about equal to that separating α^1 and α^2 Capricorni, and that I could decide when I should observe them. My memory of Mizar and Alcor was quite distinct, and as soon as I thought of those (which I did before my arrival at Kansas City) I mentally said, "A little over half the distance between them equals that between θ Cancri and the new object," which I did not doubt was Vulcan. Upon my arrival at home I immediately consulted "Webb's Celestial Objects," and was not a little surprised to find their whole distance to be less than 12′. Thus I know they were not over 8′ apart, I believe they were but 7′. I know they pointed to the sun's disk, I believe they did to his centre. I know they did not differ one-fourth of a magnitude in brightness, I believe they were exactly equal. I see them, in my mind's eye, as I then saw them, and, while consciousness endures, their image can never fade from the retina of my memory!

I consider the estimated distance in arc, made in such great haste, as valueless compared with the distance as impressed upon the mind from three comparisons, and verified by observations of a reliable character since arriving at home.

Can any error, then, be ascribed to the measurements of Watson, a skilful observer, with telescope well mounted, and with appliances for measuring, and who not only did measure the position of the new planet, but that of the sun and θ and δ Cancri (three objects in its immediate neigbourhood) as well.

Have we any right to call in question the accuracy of his circles in giving the position of the new object when they correctly gave the positions of the others?

Wherein, then, lies the discrepancy, and how can it be reconciled? Again, Watson says the planet was much brighter than θ, while the stars which I saw were of equal magnitude.

Several times since my return from the eclipse expedition I have, both in darkness and in strong twilight, examined θ, and I find no star near it, nor no two stars in its vicinity answering, in any particular, to those seen by me at Denver.

The above facts I submit to the world, and astronomers must deduce therefrom their own conclusions as to what the objects were. My own are reached, and, briefly stated, are as follows: —That the two objects seen by me were both intra-Mercurial planets, and that I did not—as was for a time supposed—see θ Cancri. Prof. Watson saw θ, and, some 42′ of arc south-east of it, another planet, and determined its position, and near to ζ Cancri still another, whose position also he fortunately ascertained, making four in all. It will not do to say, as some have intimated, that Watson saw θ Cancri, and 42′ from it a planet which I did not see, and that I, also, saw θ, and, 7′ or 8′ from it, another planet which he did not see. This reasoning appears to me untenable, for how could he have failed to see mine, when the diameter of his field was over 40′, and had θ in its centre?

If the above conclusions are true, and that four planets were discovered instead of two (as at first supposed), the question naturally arises, Which, if any one, is Lescarbault's Vulcan?

I estimated, at the time, the objects as being of the fifth magnitude, that is, as bright as a fifth magnitude star would appear in a clear, dark night. How much allowance ought to be made for diminution from atmospheric illumination I know not. I was then of the opinion that it would make a difference of at least one magnitude, but, having examined the region around θ, and finding many stars there, and several which are quite bright, not one of which I saw during the eclipse, I think that fully two magnitudes should be allowed.

In what way can these intra-Mercurial planets (of which there are probably many) be detected?

I would suggest that, on July 29 next, a determined and systematic effort be made, with large telescopes equatorially mounted, to observe θ Cancri, and, if then successful, there is hope that these planets, or some of the larger ones, may be discovered in the absence of a total eclipse, or while in transit. If

θ cannot be thus seen, then it appears to me that all time spent in their search in the sun's vicinity, except during a total or very large partial eclipse, would be time lost.

Rochester, N.Y., November 8 LEWIS SWIFT

Colour-Variation in Lizards.—Corsican Herpetology

IN a communication sent to you by my friend Mr. Wallace, under the title, "Remarkable Local Colour-variation in Lizards," published in NATURE, vol. xix. p. 4, mention is made of the well-known case of *Lacerta* (Podarcis) *muralis*, var. *faraglionensis*, only found on the Outer Faraglione of Capri, but there are many similar cases to my knowledge, and I add a note of them, for the fact, although unexplained, is one of great interest. During the last two years, while engaged in forming a complete series of the Italian vertebrate animals, I have visited and explored most of the Mediterranean islands included in the Italian sub-region, and I have invariably found that our common lizard (*Podarcis muralis*) constantly presents dark varieties *on islets adjoining small islands:* this is the case on the Scuola, near Pianosa, on the Scoglio di Mezzogiorno, off Palmarola (Ponza), on S. Stefano, off Ventotene, on the Toro, off Vacca (Sardinia), on Lisca nera, Lisca bianca, and Bottaro, off Panaria (Lipari), on Filfla, off Malta, and on Linosa, near Lampedusa. The extreme cases are those of the Faraglione off Capri and Filfla, where a nearly intense black is obtained; next comes Toro, and next Linosa; only the latter case might be explained by the "struggle for existence" theory, for the lava rocks of Linosa *are* black; but such is certainly not the case with the other islets, and, *pace* Dr. Eimer, the Faraglione is gray, while Filfla—on which I spent a pleasant day in October last—is painfully white in the glaring Maltese sun, so that its black lizards are most conspicuous. I may add that few creatures I know vary more in colour than *Podarcis muralis*, even in the same locality; two most distinct varieties occur promiscuously on the small flat islet Formica di Grosseto.

Going over my Mediterranean herpetological notes reminds me of an interesting discovery I made last summer in Corsica, an island of great interest, which, strange to say, is rarely trodden by naturalists. Most of your zoological readers will be aware that, in 1839, Prof. Savi, of Pisa, described two new species of Italian Urodela, both from Corsica, viz., *Salamandra corsica* and *Megapterna montana*. The former has been quite neglected by modern herpetologists, or else placed among the synonyma of *S. maculosa*, simply because no one had Corsican specimens to compare. Now it is evidently nearly allied to the Continental form, but *quite distinct*, as the specimens I collected testify, all of them presenting the distinctive characters pointed out by Savi forty years ago. A nearly similar lot befell *Megapterna montana*, which Savi described nearly contemporaneously with Genè's description of *Euproctus Rusconii*, from Sardinia. Buonaparte, in his "Fauna Italica," united the two under the name of *Euproctus platycephalus*, given by Gravenhorst in 1829 to a newt, *sine patria*, preserved in the Breslau Museum; and most naturalists have followed Buonaparte, especially later writers on the subject, as Strauch, De Betta, and Schreiber, whilst others, acting more wisely, stuck to Genè's name. I believe that since Savi's day no one has studied the Corsican form, whose essential characters pointed out by the Pisan naturalist, who had only two specimens to work on, were overlooked even by his contemporary, the Prince of Canino; this explains all. Last year I rambled and collected all over Corsica, and found Savi's newt quite common in all the mountainous districts; I secured about 150 specimens of both sexes and all ages, even larvæ, and on my return to Florence was much surprised to find them *quite distinct* from the Sardinian *Euproctus* I possess; this made me refer to the original descriptions, and thus I found that Savi and Genè had described two very distinct species, and described them well. The two Italian species of *Euproctus* may be thus defined:—

E. Rusconii, Genè: Parotids wanting. Skin smooth, with small whitish tubercles scattered, especially about the sides of the head and neck. Female with a small conical pointed fibular tubercle, very like a rudimentary finger. Hind fingers slender and cylindrical. Irregular dark blotches on the throat. Size somewhat larger than the succeeding species. Hab. Sardinia.

E. montanus, Savi: Parotids small but distinct. Skin rough and granular. Female with a large, obtuse, compressed fibular tubercle, more like a ridge or crest, than anything else. Hind fingers stout, broad, and flattened. Throat uniform, rusty, without blotches; often a red or yellow dorsal stripe. Hab. Corsica.

As to *Euproctus platycephalus*, Gravenh., only a careful examination of the type-specimens, if yet existing in the Breslau Museum, can settle to which form it ought to be referred, but if their locality is unknown, I believe it better to suppress the name. *Euproctus platycephalus* is said to be found in Spain, but as I have no Spanish specimens, I cannot give any opinion on that form. In conclusion, I may add that Buonaparte was perfectly right in separating from the former the North African species *T. Poireti*, which is very distinct from our Italian *Euproctus*, in the shape of the head and body, and in the complete absence of any fibular tubercle in the female; it ought to be called *Glossoliga Poireti*. Florence, November 16

Commercial Crises and Sun-Spots

REFERRING to Prof. Stanley Jevons's article upon "Commercial Crises and Sun-spots" in NATURE, vol. xix. p. 33, I beg to draw your attention to the inclosed circular which I issued to my subscribers in April last.

The figures relating to the "Failures in England and Wales," were compiled by my clerks, under my own direction; those relating to the failures in the United States and Canada were supplied by Messrs. R. G. Dun and Co., of New York and London, and it may be observed how nearly they agree (*i.e.*, the failures in England and Wales, and those in the United States and Canada) in their fluctuations, and that there is an agreement between both sets of figures and the sun-spot period.

I have not been able to obtain similar figures for continental states, but I have observed that the complaints of depression in trade there agree, in substance and in time, with those in this country and North America. I have also noticed similar complaints from the southern hemisphere, especially New Zealand.

I refer to Dr. Hunter's suggestion of an Indian famine period in my circular, but I do not find that the famine period in India agrees, in point of time, with the depressions in the temperate zones; it is very probable that the excess of sunshine which produces drought and famine in India has an opposite effect on the prosperity of England and all other countries lying between the same isothermal lines, and that the more moderate degree of sunshine which may suit the Indian cultivator is insufficient to properly ripen English wheat and other produce (oats excepted).

Since April last I have taken several opportunities of ascertaining from agriculturists the effect of the variations in the sun-spots upon their yield of wheat, &c., and I find an agreement between them that during these years of minimum sun-spots the yield has proved bad when thrashed out, in consequence of the kernels being much smaller than in other years. I do not know whether the test has ever been tried or not; if not, I would suggest that some scientific observer should weigh an ounce, or a few ounces, of the kernels of each kind of grain grown in England every year, and count the number of them. I think it would be found that in years of maximum sun-spots wheat and barley kernels weigh their heaviest and oats their lightest, and that these proportions would be reversed in the years of minimum sun-spots. The difference in each kernel or in an ounce of them may, taken alone, appear trifling; but if it is an indication of the difference in the yield of the harvest throughout the whole kingdom, it may be a fact of the greatest importance as showing the cause of the cyclical variations in the prosperity of the country, and it may be of great value to land-owners and agriculturists generally as a guide in the rotation of crops and in allowing fields to lie fallow.

It is in this direction that I look for the causes of commercial depression. The whole of our "home" trade is dependent upon internal prosperity, and likewise a large proportion of our "foreign" trade. Other causes may have some effect upon either or both, such as peace or war, trade-unionism, bank-management, and the like; but the influence of the sun is too far-reaching and too powerful to be checked thereby. Man, by studying the working of its influence and power upon his daily life, may learn how to guard against much of the distress which periodically recurs. JOHN KEMP

Aspley Guise, November 16

"*London, April*, 1878

"*Failures in England and Wales*

"We append a Summary of the failures in England and

Wales, which it has been our duty to publish in *Kemp's Mercantile Gazette* during the past eleven years:—

Year.	1st quarter.	2nd quarter.	3rd quarter.	4th quarter.	Totals.
1867	3,981	4,081	3,555	4,233	15,850
1868	4,091	4,131	4,139	3,501	15,862
1869	3,819	3,997	3,495	5,207	16,518
1870	2,804	1,589	1,773	1,985	8,151
1871	2,142	2,191	1,837	1,994	8,164
1872	2,192	1,980	1,795	2,145	8,112
1873	2,354	2,299	2,054	2,357	9,064
1874	2,193	2,428	2,339	2,290	9,250
1875	2,331	2,277	2,133	2,453	9,194
1876	2,744	2,573	2,670	2,861	10,848
1877	2,829	2,856	2,610	2,952	11,247
Total for 11 years					122,260

. . . .

"The question occurs: Does the number of failures in a year depend upon natural causes? that is to say, Would the number rise and fall periodically according to the state of trade (or national prosperity) if the Bankruptcy Law remained constant? Whenever failures have become frequent, complaints have been made against the Law, and not without reason, but many who complain ignore the existence of any other cause. We compared the foregoing figures with the scientific tables recently published in NATURE, from the pen of Prof. Balfour Stewart,[1] and, being struck with the coincidence in their fluctuations, we further compared them with the statistics published by Messrs. Dun and Co., of New York, of the failures in the United States during the past eight years,[2] which period, being that of the existence of our present Bankruptcy Law, affords us a fair opportunity for making a comparison. Messrs. Dun and Co. report the following as the total failures in the United States during this period:—

1870, Number of Failures,	3,551
1871, ,, ,,	2,915
1872, ,, ,,	4,069
1873, ,, ,,	5,183
1874, ,, ,,	5,830
1875, ,, ,,	7,740
1876, ,, ,,	9,092
1877, ,, ,,	8,822

"Evidently the same causes which were at work in England to depress trade and overwhelm the struggling and improvident classes, were equally effective in other countries—similar complaints of depression come to us from every part of the globe.

"The discussion which has arisen out of Dr. Hunter's suggestion of a 'famine period' in India, has brought to the public some knowledge of the existence of natural periods or cycles, of an average duration of 11·9 years each. The suggestion that England is affected with the same regularity is but reasonable, and although fortunately for us as a nation the effects do not produce famine, it appears evident that some degree of suffering is caused, and that the number of failures is thereby materially increased—the commercial panics which have occurred with about the same regularity furnish further evidence that this is the case.

"If we make due allowance for the excessive number in the last quarter of 1869, caused by the change in the Law, we find that the maximum number of failures in the last cycle occurred in the year 1868, which was the year succeeding the natural minimum; hence we may conclude that about a year is required for the full effect of the natural depression to be reproduced in commerce. The twelve months from October 1, 1867, to September 30, 1868, appear to have been more serious to commercial men than either of the complete years, according to the number of failures:—

"In the 4th Quarter of	1867	there were 4,233	failures.
,, 1st ,,	1868	,, 4,091	,,
,, 2nd ,,	1868	,, 4,131	,,
,, 3rd ,,	1868	,, 4,139	,,
Total		16,594	

"These data indicate that we have not yet reached the worst of the present period—assuming that it runs an average length, we have to endure an increasing number of failures which will not reach its maximum until the fourth quarter of 1879."

JOHN KEMP AND CO.

Since this was written I have had counted the number of failures gazetted since January 1, 1878, and I find that they are *2,042* in *excess* of the corresponding period (January 1 to November 19) in the preceding year. J. K.

Strange Properties of Matter

THE following are two experiments which will, perhaps interest some of your readers:—

Experiment No. 1.—The "Welding" of Metals at Low Temperatures

Some time ago, in order to estimate the amount of hydrocyanic acid in a solution, I precipitated it with silver nitrate. After having filtered and washed the precipitate, I reduced it to the metallic state by heating to the required temperature. Just as I was about to allow it to cool, I noticed a small piece of dirt among the reduced silver. In order to separate them, I took a thin platinum wire, and pushed the silver to one side, but on attempting to take the wire away the silver remained in contact with it. As I thought this curious, I tried the following experiment. I took a piece of silver foil about one centimetre square, placed it in an inverted porcelain crucible lid, and heated it to about 500° C.; then I brought into contact with it the extremity of a thin platinum wire, and to my astonishment the wire raised the silver from the lid, and it remained in contact when cold, as the silver was so very much below its melting-point; the above fact caused me some surprise, and I could not satisfactorily account for it.

I wrote to Sir W. Thomson, F.R.S., giving him a description of the above experiment, and in return I received a reply asking me to come and show him the experiment at his laboratory. I accordingly went up to the Glasgow University, and repeated it before him. He was very much interested, and advised me to write to NATURE, giving a description of the experiments. Sir W. Thomson gave the following explanation—That it was a remarkable case of "cohesion," the two metals, in fact, "welding," although the temperature was far below the melting-point of silver. The above experiment can be performed successfully at lower temperatures than 500° C., if smaller pieces of foil are taken. Other metals, for instance, copper and aluminium, cohere to silver in the same manner as platinum, but less strikingly.

Experiment No. 2.—A Curious Resonator

Some months ago I made the following experiment:—I took a small tuning-fork and struck it on the table. After the note had died away, so that it was no longer audible, I held the fork in the tip of the flame of a Bunsen burner, when the note was given out, so that it could be heard at some distance. I showed Sir W. Thomson this experiment, who gave the following explanation—That owing to the difference in density of the gases in the flame, the flame acted as a resonator, and so the note was emitted.

It seems to me that experiment No. 1 could be made the subject of an interesting research, but as I am wholly engaged in commercial pursuits, I am unable to take it up.

CHARLES A. FAWSITT

Glasgow, November 12

Galvanometer for Strong Currents

I MUST confess that I was surprised by Mr. R. E. Baynes' communication, in NATURE, vol. xix. p. 33, that the galvanometer I have proposed in NATURE, vol. xviii. p. 707, has already been described. Before writing my article I have searched a good many books and journals relating to the subject without finding an allusion to any such instrument. Since Mr. Baynes drew my attention to "The Elements of Physical Manipulation," by Prof. Pickering, of the Massachusetts Institute of Technology, U.S., I have procured this book and find that it certainly does contain the theory of a galvanometer like mine, with the coil moving round a horizontal axis. As far as I know, such an instrument has, however, not been practically employed either in this country or on the Continent before I introduced it, though its want must have been much felt for some time past. This seems to show that Prof. Pickering's description of the instrument has not been brought to the general

knowledge of electricians. If, therefore, my article in NATURE, at a time when electric currents of great strength are being so widely introduced into practical working, has contributed to make electricians acquainted with this form of galvanometer, I shall not regret the time I have spent in theoretically and experimentally investigating this subject. Prof. Pickering alludes in his book to the improper *dip motions* of the needle as a defect in his form of galvanometer; I think I have obviated this by pivoting the axis of the needle at both ends. Since communicating the results obtained with my *experimental* instrument, more elaborate instruments have been constructed and found very useful in many instances where the ordinary forms of galvanometers would not have answered the purpose. EUGEN OBACH

Woolwich, November 19

Utilisation of the African Elephant

I have just read some remarks in NATURE (vol. xix. p. 54) on the utilisation of the African elephant, which I think are worth considering. Judging from the specimens in the Regent's Park Gardens, which I suppose have not been selected in any way, and are therefore only average samples of the African species, I should say that the African elephant would prove hardier and capable of more work than the general run of Indian elephants. I was surprised to find that the two African elephants I saw in the Regent's Park were what the mahouts call "Dohara Band," which I would translate "double constitution." I do not think that more than five per cent. of Indian elephants are placed in this class. It is very rare indeed to see an elephant of this class in a Government Feelkanah, or in the hands of any European, because wealthy natives value them so highly and give such enormous prices for them, that even when caught by a Government keddah officer they are often sold on account of the fancy prices they fetch. The "Dohara Band" elephant will do a wonderful amount of work on a small quantity of food, and stands fatigue and exposure to the sun far better than any other sort.

To commence elephant-catching operations in Africa, six "koonkies," *i.e.*, elephants trained for catching purposes, would be required, and about twenty men from Assam or some other jungle district of Bengal would be sufficient. With this establishment it would be possible to catch and train at least two hundred elephants in the course of twelve months.

H. L. JENKINS

Clanacombe, Kingsbridge, South Devon, November 24

OUR ASTRONOMICAL COLUMN

ORBITS OF BINARY STARS.—In a communication to *The Observatory*, Dr. Doberck, of Col. Cooper's Observatory, Markree Castle, has summarised the results of the investigations on the orbits of the revolving double stars which have occupied him between three and four years, and which he has conducted with so much skill and laborious application. In a climate where the skies are too irregularly favourable to allow of an astronomer occupying himself wholly upon observations, it would be difficult to name any more interesting work to which he could devote his leisure, than such a revision of the elements of the binary systems. Dr. Doberck's account of his methods in different cases will be of much service to any one who may engage upon similar researches. He has found no reason to detract from the value of the early, graphical method of Sir John Herschel; on the contrary, instances are mentioned where it has been of the greatest service in tracing out the general form of the orbit, for correction by more refined processes, as in the difficult case of Σ 1768: indeed, Dr. Doberck considers it superior to the second method given by Herschel from its admitting of the weights being approximately taken into account with ease. In a provisional orbit for the close double star Σ 3121, the period assigned is thirty-seven years; at present we know of only two more rapid binaries. Some of [the orbits included in Dr. Doberck's paper, have been made the subject of communications to the Royal Irish Academy, and have been published in the *Transactions*.

LALANDE'S STARS, NOS. 5,499 AND 45,400.—Mr. J. E. Gore writes suggesting variation in both these objects. In examining the question of variability of any of Lalande's stars, Mr. Gore will find it necessary, in the first instance, to have recourse to the original observations as printed in the "Histoire Céleste," there being many errors in the reduced catalogue. Thus, No. 5,499 appears through a misprint at p. 246, where the transit at the third wire is given as 2h. 47m. 45·2s., instead of 2h. 42m. 45·2s. The star is really No. 788 of Weisse's Bessel. The following star is also thrown out by a similar error in the time of transit, so that Lalande, 5,520, requires a correction of – 5m. in R.A. With regard to No. 45,400, the suspicion of variability is probably occasioned by a misprint in the "Histoire Céleste," since Piazzi, Bessel, and others estimate the magnitude the same as at present.

THE ANNULAR ECLIPSE OF JANUARY 22, 1879.—The first of the annular eclipses of the ensuing year, a return of that of January 10, 1861, which was central in Australia, commences in Uruguay, whence the belt of annular phase traverses the South Atlantic, passing over Tristan d'Acunha, the few inhabitants of which islands may probably be startled by seeing the sun transformed into a narrow luminous ring while he is high in their heavens. The central line crosses the African continent in the direction of Pemba Island, north of Zanzibar, where the annularity will continue nearly three minutes: the middle of the eclipse at 4h. 6m. P.M., local mean time.

GEOGRAPHICAL NOTES

THE Council of the Royal Geographical Society have determined to commence, on January 1, 1879, the monthly issue of a new series of their *Proceedings*, under the title of *The Proceedings of the Royal Geographical Society and Monthly Record of Geography*. The latter part of this title will, we believe, fairly indicate the nature of the contents, which will include the papers read at the evening meetings, original articles, geographical notes, obituary notices, proceedings of geographical societies, and brief analytical notes on new books and maps. Each monthly number will be illustrated with one or more maps, and no doubt in this respect endeavours will be made to meet the wants of a public larger than that contained within the ranks of this popular society, which now numbers some 3,400 members.

IN connection with this we regret to announce that this month's number of the *Geographical Magazine* brings the career of that journal to a close. This regret, however, is considerably mitigated by the fact that the new form of the Geographical Society's organ is intended to take the place of the journal which for so many years has been so ably conducted by Mr. C. R. Markham. Mr. Markham deserves great credit for his disinterestedness in continuing to carry on a journal which aimed so successfully to be the organ of scientific geography in this country. The volumes will form a valuable record of the progress of geography for the period over which they extend. In the December number Mr. Markham gives an account of the career of the journal since its first start as *Ocean Highways* in 1870. We trust that the new organ will prove a worthy successor of its predecessor, and that while giving due prominence to geographical news, the conductors will aim at bringing geography under the guidance of sound scientific principles.

THE Church Missionary Society have recently received from Mr. A. M. Mackay, of their Nyanza Expedition, the journal of his experiences, extending from December 31, 1877, to May 16, 1878, in which occur some useful suggestions to African travellers, as well as information of considerable interest to geographers. On April 30 Mr. Mackay reached Uyui, after a hurried and tedious tramp

of 350 miles, undertaken with the view of aiding the Rev. C. T. Wilson, and he promises a detailed account of his troubles then on another occasion. In the course of this march he had to cross the extensive wilderness of Mgunda Mkali, which he describes as being for the most part not merely a swamp, but this year more under water than above it. Day after day the party waded and splashed through mud and water, now over the ankles, sometimes up to the knee, and here and there up to the waist or higher. Hopeless and still more hopeless, Mr. Mackay remarks, the wading seemed to become, and he found that they were crossing what was neither more nor less than the source at once of the Nile, the Congo, and the Rufiji. This gigantic boggy plain or moss Cameron calls the Nya Kun Swamp, and, where Mr. Mackay crossed it, in S. lat. 5° 20′, his aneroids recorded an average elevation of 4,000 feet exactly. To the north, in Usukuma, the swamp narrows itself into the sluggish Lewumberi River, the most southerly of the sources of the Nile. From this swamp, too, the rapid Mdaburu River takes its rise, and flows southward into the Ruaha, in Unyoro, and Uhehe, and thence to the Indian Ocean, where it is known as the Rufiji. A day's march east of Tura Mr. Mackay found the swamp contract to a breadth of 300 yards, with increased depth, and slight indications of flow to the southward; it then rounds to the west, steering clear of Iiwe-la-Singa, and, after two more days, it was crossed—a flooded, five-armed river, flowing rapidly north at an altitude of 3,700 feet. Here it is called the Nghwàla River by the Wanyamwezi, from the number of partridges on its banks. In Speke's map alone it would seem that the true course of the river is indicated; it flows north-east to Mirambo's country, where it is known as the Ngombe (*i.e.*, ox) River, and finds its way into the Malagarasi, thus aiding that river in bringing Lake Tanganyika nearer to permanent overflowing, when the Lukuga—which has been such a bone of contention to two great travellers—will no longer be a swamp but a decided stream, and the waterline of the Congo will run from Loango on the West Coast to the confines of Ugogo.

THE London Missionary Society have received a letter from the Rev. J. B. Thomson, dated from Ujiji, announcing the safe arrival on August 23 of the main body of the Society's expedition at its destination on Lake Tanganyika. Though, as will be remembered, this expedition met with a long series of disasters and delays in the coast region, they have now been successful in performing one of the quickest and most prosperous journeys from Mpwapwa to Ujiji, having been but seventy-three days on the road. Messrs. Thomson and Hore have already found an apparently healthy site for their station close to Kinegoma Bay, and about three miles from Ujiji.

WE learn from a Japan paper that an American gentleman has been engaged for some time past in surveying the Island of Yezo, as well as in making geological investigations. The result is said to be that there are 7,000 square miles of land fit for agricultural purposes, and 6,000 suitable for pasture, while there are 5,000 square miles of forests and 9,000 of volcanic mountains and mineral country. An impression appears to prevail that the Government wish to encourage emigration to this thinly-populated part of the Japanese empire.

AS an erroneous impression prevails that nothing is known of the scientific work done by the Portuguese African expedition previous to the date mentioned in last week's NATURE, it may be interesting to give, as instances of the service which they are rendering to geography, the positions of some of the places determined by Senhor Serpa Pinto and his colleagues:—Benguela, long. 13° 25′ 20″ 45‴, lat. 12° 34′ 17″, alt. 7 metres; Dombe Grande, long. 13° 7′ 45″, lat. 12° 55″ 12′, alt. 98 metres; Quillenques, long. 14° 5′ 3″, lat. 14° 3′ 10″, alt. 900 metres; Caconda, long. 15° 1′ 51″, lat. 13° 0′ 44″, alt. 1,678 metres; Bihé, long. 16° 49′ 24″, lat. 12° 22′ 40″, alt. 1,670 metres. The longitudes are stated to be chronometrical.

DR. EDWIN R. HEATH, of Wisconsin, is about undertaking the exploration of the Beni and Madre di Dios Rivers of Brazil, his sojourn in South America some years as secretary of legation in Chili giving him excellent advantages for this purpose. Dr. Heath had arranged to visit South America with Prof. Orton, but was detained, and he now desires to carry out some of the work that the untimely death of that well-known explorer has left uncompleted.

THE latest advices from Mr. Frederick A. Ober, of whose explorations in the West Indies on account of the Smithsonian Institution we have given notice from time to time, were from Point à Pitre, Guadeloupe, on September 23. He was about to leave for the United States, expecting to arrive some time between the middle and end of October. Since his last report he has obtained quite a number of additional collections, and hoped to complete the material for the proposed catalogue of the birds of the West Indies. So far the collections sent forward by him to the Smithsonian Institution have been found to contain some seventeen undescribed species of birds, as determined by Mr. George N. Lawrence, of New York.

AN interesting account of a recent visit to Pitcairn Island by Admiral De Horsey in the *Shah*, forwarded to the Admiralty, will be found in yesterday's *Daily News*. The people are evidently as primitive and well-conducted, and on the whole as comfortable as ever.

IN a previous number we referred to a work of great geographical interest—"Die Sahara, von Oase zu Oase," by Dr. Joseph Chavanne, published by Hartleben, of Vienna. At that time the work was in course of publication, and we refer to it now to announce its completion in twenty parts. The last parts are in every way equal to the earlier ones, and if anything the interest is rather increased than otherwise. The work contains numerous woodcuts, besides seven coloured plates and a map of the great desert; its perusal will be found extremely attractive by any one taking interest in geographical science. The exact route which Dr. Chavanne describes is the following:—The travellers start from Tripolis through the Fezzan to Mursuk, then westward to Rhat, the land of the Tuareg or Imoshag. From Rhat they turn northward to Rhadames, thence to Biskra in Algeria. Here the travellers again turn their backs to the Mediterranean and proceed in a south-westerly direction by way of El Aruat and El Golea to Insalah. From Insalah they go to Tafilet, in the extreme north-west of the desert, and thence many thousand miles to the south to Timbuctoo. The Oasis of Air or Asben is the next station, situated due east from Timbuctoo, then Tibesti, the land of the Tebbu. Thence they turn to the northeast to the Jupiter Ammon Oasis, which is the furthest point to the east reached. The travellers then turn westward again and return to Tripolis by way of Audschila.

ON THE DEVELOPMENT OF THE GARPIKE

THE gar or bony pike of North America is one of the most interesting of living fishes. The best known species of the genus to which it belongs is the *Lepidosteus osseus*. This species owes the grammatical form of its scientific name, and, indeed, its first scientific description to the elder Agassiz, and we have now to record the filling up of the last details of its life-history to the younger Agassiz. Known for over three-quarters of a century, it has been only within the last few months that the young fish as they escape from the egg have been

seen, and it has been the good fortune of Alexander Agassiz to succeed in hatching the eggs and raising the young until they showed at least the principal structural peculiarities of the adult. A short account of the chief facts in connection with this stage of the bony pike's history will appear in the forthcoming number of the *Proceedings* of the American Academy of Arts and Sciences; from an advance copy we cull the following details:—The spawning-ground selected for observation was the Black Lake, at Ogdensburgh, N.Y. Mr. Garman, who describes the scene, and Mr. Blodgett, who rendered most essential assistance, deserve the thanks of every naturalist. The eggs collected were carried by the hand in pails from Ogdensburgh to Cambridge, where their progress was watched by Prof. A. Agassiz.

The fish began to spawn about May 18. Little projections of granite stand out here and there into the lake. The frosts from time to time have broken off from these, small angular blocks, which lie piled together under the water at depths varying from two to fourteen inches. Into these shallows the female fish would come, each of them attended by two males. While very timid when in deep water, they seemed to be courageous to recklessness when they approached the shallows. On they would come in threes, when rising to the surface of the water, and thrusting their bill out of it they would open this widely, then take in air, and close it with a snap. In some few cases three or four males would be in attendance on one female, but much more often there would be but two, and these would swim resting on either side of the female fish, their bills reaching up toward the back of her head. At times the water would be lashed into all directions with their conjoined convulsive movements. The eggs when laid were excessively sticky; to whatever they happened to touch they stuck, and so tenaciously, that it was next to impossible to release them without tearing away a portion of their envelopes. It is remarkable that, as far as could be seen, there was, on and about the spawning ground, a complete absence of anything that might serve as food for the young fish.

Of the quantity of eggs brought to Cambridge, only thirty hatched, and not one of those artificially fecundated was hatched. In Prof. A. Agassiz' anxiety not to spoil this interesting experiment he did not venture to examine any of the fresh eggs; so that the history of their segmentation and very early development remains to be worked out. The envelope of the eggs is very opaque and of a yellowish green, like that of toads. Of the thirty hatched out by the end of May, twenty-eight were alive in the middle of July last. When first hatched the young fish possesses a gigantic yolk-bag, and the posterior part of the body presented nothing specially different from the general appearance of any ordinary bony (teleostean) fish of the same age; but the anterior part was most extraordinary: it looked like a huge mouth cavity, extending nearly to the gill opening, and crowned by a depression like a horse's hoof in outline, along the margin of which were a row of protuberances acting as suckers. The moment the young fish was hatched it attached itself to the sides of the vessel by means of these, and would hang immovable. The eye was not very advanced, the body was transparent, the gill covers were pressed against the sides of the body; the tail was slightly rounded, the embryonic fin is narrow, and there were no traces of embryonic fin rays; the olfactory lobes were greatly developed and elongated as in sharks and skates; the chorda was straight. On the third day the body became covered with minute black pigment cells, and then was noted the first traces of the pectoral fins, and the snout became more elongated; the great yolk-bag was greatly reduced in size. About the fifth day were seen traces of the caudal, dorsal, and anal fins. Gradually the snout became elongated, the suckers concentrated, and the disproportionate size of the sucking disc became reduced, so that when about three weeks old it became altogether more fish-like. The sucking disc was now reduced to a swelling at the top of the upper jaw, the yolk-bag had disappeared, the gill covers extended well up to the base of the pectorals—these latter were in constant motion, and the tail exhibited the same rapid vibratile movements. The young fish now begins to swim about, and is not so dependent upon its sucking disc, and at last this only remains as a fleshy globular termination on the snout. At this stage, too, the young have the peculiar habit of the adult fish of coming to the surface to swallow air. When they go through the process under water of expiring this air they open their jaws wide and spread their gill-cover, and swallow as if they were choking, making violent efforts, until a minute bubble of air has become liberated, when they become quiet again. Their growth is rapid. Within a month the teeth made their appearance, and some of the fin-rays on the fringe of the pectorals were to be seen.

Prof. A. Agassiz draws the following conclusions from these observations:—"That notwithstanding its similarity in certain stages of its growth to the sturgeon, notwithstanding its affinity with sharks by the formation of its pectorals from a lateral fold, as well as by the mode of growth of the gill openings and gill arches, the Lepidosteus is not at all so far removed as is generally supposed from the bony fishes." The memoir is illustrated by five plates containing some forty-five figures, and is only to be regarded as a preliminary account, but it is a preliminary account of such exactness, importance, and interest, that no apology is necessary for bringing it at once under the notice of our readers. This memoir was presented to the American Academy as recently as October 8 last. E. PERCEVAL WRIGHT

THE MUSIC OF COLOUR AND MOTION

AT the Physical Society, on November 23, 1878, Prof. W. E. Ayrton, late of the Imperial Engineering College, Tokio, Japan, read a paper, written by himself and Prof. J. Perry, of the same college, on "The Music of Colour and of Visible Motion." The authors began by pointing out the well-known fact that emotion is excited by moving bodies, and they believed that, upon this basis, a new emotional art would be created which would receive a high development in the far distant future. All methods of exciting emotion could be cultivated; but of these, music, by reason of the facility with which its effects could be produced, had alone been highly perfected by the bulk of mankind. Sculpture and painting are not purely emotional arts, like music, inasmuch as they involve thought. It would take a long time and much culture for the eye to behold moving figures with similar emotional results to those of the ear on hearing sweet sounds; but time and culture only might be necessary. It might be due to their neglect of this emotional tendency that the Western nations felt little emotion at moving visual displays. For among the Eastern nations they had entertainments consisting of motions and dumb show, which, although incomprehensible and even ludicrous to the European, powerfully affected the feelings of a native audience. In Japan the authors had seen whole operas of "melodious motion" performed in the theatres, the emotions being expressed by movements of the body, affecting to the audience, which were quite strange to them. The accompanying orchestral music was, withal, displeasing to the authors, while, on the other hand, Western music is mostly displeasing to the Japanese.

The emotions produced by rapidly-moving masses, such as a train bowling up to a bridge, or by changing colours, as in sunsets, have been felt by all, and those excited when the moving bodies are very large do not

seem to be producible by anything else in nature. Harmonic instruments have been constructed to exhibit the combination of two or more pairs of harmonic motions to the eye; for example, Blackburn's pendulum, Lissajous' forks, Wheatstone's kaleidophone, Yeates' vibrating prisms, Donkin's and Tisley's harmonographs, and Hopkins' electric diapason. Prof. Ayrton illustrated his remarks by exhibiting these instruments in action. The pendulum traced out the complex path of the combined motions by a jet of falling sand, the forks or prisms by a moving beam of light thrown on a screen, the kaleidophone by a bright bead, and the harmonograph by the involutions of an aniline pen. With none of these and such like instruments, however, is the production of mere emotion the end in view; and in some of them no change can be made in the periods of the pairs of harmonic or periodic motions combined without arresting the instrument, a proceeding which in music would be analogous to stopping the tune at the end of every chord. There is no provision either for changing the amplitude or phase, equivalent in music to an inability to render, at will, a note forte or piano, or rather as it is not only the strength of the entire note, but even the amplitude of the various component harmonics that these instruments cannot regulate, it would be as if in music there was the probability of a note marked in the score as piano for the flute being rendered by a loud blast from a trumpet. A successful instrument in the new kinematical art must at least visibly render changes in period, amplitude, and phase of the harmonic motions represented. Profs. Perry and Ayrton had designed an instrument, which is now in Japan, for effecting these required changes in a combination of harmonic motions given to a moving body, and which they claimed to be the first musical instrument of the visual art in question. They had not given it a name yet, because the nomenclature of the subject was uninvented. Photographs and diagrams of this instrument were exhibited to the meeting. It consists of a mechanical arrangement of sliders, pulleys, and cords, whereby two motions, one along a vertical, and the other along a horizontal line, and *each* consisting of the *sum* of a number of harmonic motions the *period*, *amplitude*, or *phase* of *any one* of which can be varied at will, are compounded in the resultant motion of a suspended pane of glass. A black circle painted on the pane is intended to represent the moving body as projected against a wall or screen behind. The sliders controlling the motion of the pane are actuated by a revolving barrel, the periphery of which is carved according to mathematical principles, so as to give the different harmonic motions to the sliders in one revolution. The motion is further regulated by shifting the sliders either parallel to the axis or at right angles to the radius of the revolving barrel; and by the angular velocity of the barrel. In this way the period, amplitude, and phase of the component motions of the glass either in a vertical or horizontal direction, may be changed at will, and almost immediately. Other kinds of periodic motions may be compounded in a similar way. Prof. Ayrton also suggested other forms of apparatus for this purpose. Numberless combinations of graceful motions producing emotional effects on the beholder can by its means be given to a visible body. It is the intention of the authors to construct an improved form of the apparatus, and to arrange for the blending of colour with the moving body to heighten the emotional influence; for example, they purpose having changing mosaics of different hues, thrown upon the screen for a background to the black spot. This can be done by means of an instrument similar to the chromotrope with its revolving sheets of parti-coloured glass. In conclusion Prof. Ayrton said that there might yet be invented many different ways of producing these spectacles, and there was no reason why a whole city full of people should not enjoy these displays projected upon the clouds overhead.

THE SWEDISH NORTH-EAST PASSAGE EXPEDITION

FROM letters despatched from the mouth of the Lena by Prof. Nordenskjöld on August 27, which have just been published in the Gothenburg *Handels Tidning*, we learn that the *Vega* accompanied by the *Lena* left Dickson Harbour, at the mouth of the Yenissej, on August 10, the weather being fine. On the 11th ice was seen, but it consisted almost exclusively of bay ice which did not obstruct navigation, which, however, was rendered difficult by a thick fog. The salinity of the water began gradually to increase and its temperature to fall. Organic life at the bottom grew richer at the same time, so that Dr. Stuxberg on the night between August 13 and 14, while the vessel lay anchored to a drift-ice floe, collected with the swab a large number of beautiful pure marine types; for example, large specimens of the remarkable crinoid, *Alecto eschrichtii*, numerous asterids (*Asterias linckii* and *panopla*), pycnogonids, &c. The dredgings near the land now too began to yield to Dr. Kjellman several large marine algæ. On the other hand the higher plant and animal life on land was still so poor that the coast here forms a complete desert in comparison with the rocky shores of Spitzbergen or West Novaya Zemlya. Auks, rotges, loons, and terns, which are met with on Spitzbergen in thousands upon thousands, are here almost completely absent. Gulls and *Lestris* which there fill the air with continual sound occur here only sparingly, each with two species, and it appears as if they quarrelled less with one another. Only the snow-bunting, six or seven species of waders, and a few varieties of geese are found on land in any great numbers. If we add a ptarmigan or two, a snowy owl, and a species of falcon, we have enumerated the whole bird fauna of the region, at least so far as the Swedish expedition have been able to ascertain it. Of warm-blooded animals in the neighbouring sea, only two walruses and some seals, *Phoca barbata* and *hispida*, were met with. There is probably great abundance of fish. Cosmic dust was sought for on the ice without success, but there was found upon it some yellow specks which, on examination, were found to be a coarse-grained sand, consisting exclusively of very beautifully-formed crystals up to two millimetres in diameter. The nature of these crystals was not ascertained, but it was evident that they are not formed of any ordinary terrestrial mineral, but possibly of some substance crystallised out of the sea-water during the severe cold of winter.

The *Vega* lay at anchor from August 14 to 18 in a harbour named Actinia Harbour, from the number of these animals brought up by the dredge from the sea-bottom. This harbour is situated in a sound between Taimyr Island and the mainland. The land was free of snow, and covered with a greyish-green turf formed of a close mixture of grasses, mosses, and lichens, forming a reindeer pasture much superior to that of the valleys in Spitzbergen which abound in reindeer. Only a few reindeer, however, were seen here, probably owing to the presence of wolves. The number of phanerogamous plants is exceedingly small; the moss and especially the lichen vegetation, on the other hand, abundant enough. Actinia Harbour is an excellent position for a meteorological station. The fog still continuing, the *Vega* and the *Lena* sailed again on the 18th, and reached Cape Chelyuskin on the 19th, anchoring in a little bay which indents the low promontory, dividing it into two parts. The western point was found to be situated in 77° 36′ 37″ N. L., and 103° 25½′ E. from Greenwich, and the eastern in 77° 41′ N. L., and 104° 1′ E. L. Inland the mountains appeared to rise by degrees to a height of 1,000 feet. These mountains, as well as the plains, were free of snow. Only here and there were to be seen large white patches of snow in hollows on the mountain sides or in some small depression on the plains. At the beach, however, the ice-foot still remained at most places.

The soil of the plains is clayey, partly bare, and cracked into more or less regular hexagonal figures, partly covered by a turf of grass, mosses, and lichens resembling that at the last landing-place. The rock here, however, was not granite, but upright unfossiliferous schistose strata rich in crystals of sulphide of iron, and crossed at the extremity of the cape by thick quartz veins. Dr. Kjellman could not find here more than twenty-four species of phanerogamous plants, most of them distinguished by a disposition to form compact half-globular tufts. The lichen vegetation was also, according to Dr. Almquist, monotonous, though luxuriantly developed. It almost appeared as if the plants of the Chelyuskin peninsula had attempted to wander farther toward the north, but halted when they met the sea, at the very outermost point. For here were found within a very limited space nearly all the plants, both phanerogams and cryptogams, which the land had to offer, and many of them were sought for in vain farther up on the plains.

Animal life on land rivalled the higher plant life in poverty. Of birds there were seen only a number of *Phalaropus*, some species of *Tringa*, a *Colymbus arcticus*, a very numerous flock of *Anser bernicla*, a few eiders, and the remains of a snowy owl. In the neighbouring sea, which was almost free of ice, were seen a single walrus, two shoals of white whales and some few seals (*Phoca hispida*). It, too, was here evidently very poor in warm-blooded animals. On the other hand the dredge brought up from the sea-bottom various large algæ (*Laminaria agardhi*, &c.), and a large number of lower animals, among them very large specimens of *Idothea entomon*, an isopod, which also occurs in the Baltic and the large Swedish lakes, and is looked upon as an evidence that during the ice age they were connected with the Polar Sea. The algæ obtained were interesting as affording further proof of the incorrectness of the view which long prevailed, that the Siberian Polar Sea was quite devoid of the higher algæ.

On August 20 the voyage was resumed, the course being set east by south, in the hope of falling in with a continuation of the new Siberian Islands. Drift-ice was soon met with, and by the morning of the 23rd it was found impossible to proceed further in that direction. An attempt was now made by sailing in a northerly and north-westerly direction to get out of the ice-field, and in about twenty-four hours the *Vega* was again in open water, and the same day land was sighted. The land was found to be the north-eastern extremity of the eastern Taimyr Peninsula, lying in about 76° 30′ N. L., and about 113° E. of Greenwich. The sea was completely free of ice for a distance of 15′ or 16′. Fine mountains 2,000 to 3,000 feet high were seen some distance inland. These, like the plains below, were free of snow to their highest summits. Some small glaciers were believed to be seen, but they ended at a height of about 800 to 1,000 feet above the sea.

Animal life now began to be very abundant. Dr. Stuxberg had, while the vessel lay anchored to a floe in the drift-ice-field, brought up from a depth of 35 fathoms an unexpected variety of fine marine animal types, among them three specimens of a crinoid supported on a stalk, probably young individuals of *Alecto eschrichtii*, which also was found in innumerable full-grown specimens, masses of asterids (for instance *Solaster papposus*, *endeca*, *furcifer*, *Pteraster militaris*, *Asterophyton eucnemis*), and of the otherwise exceedingly rare *Molpadia borealis*, a colossal pycnogonid of 180 millimetres diameter, &c. Not less abundant was the lower animal life at a smaller depth though the forms were partly different. The animals occurring here were evidently pure Polar Sea types without any immigration whatever from southern seas, such as has doubtless taken place in the case of the fauna of Spitzbergen.

On August 24 land was sighted, which was found to be Preobraschenski Island, near the mouth of the river Katanga. From this point to the mouth of the Lena the depth was only from 5 to 8 fathoms.

To judge from the experience of the voyage there is no more ice on the Siberian coast during the latter part of summer than in the White Sea during midsummer. Besides the ordinary observations of the temperature of the sea-water at the surface in connection with the common meteorological observations made six times in the twenty-four hours, the temperature and salinity of the water at different depths were determined two or three times a day. When the depth amounts to at least 30 metres the temperature at the bottom is found to vary between $-1{\cdot}0°$ and $-1{\cdot}4°$ C. The specific gravity of the water amounts there to 1·026—1·027, the salinity being little less than that of the water of the Atlantic Ocean. On the surface the temperature is exceedingly variable:—At Dickson Harbour $+10°$, a little south of Taimyr Sound $+5{\cdot}4°$, among the drift ice off that sound $+0{\cdot}8°$, off Taimyr Bay $+3{\cdot}0°$, at Cape Chelyuskin $+0{\cdot}1°$, off Katanga Bay $+4{\cdot}0°$, between Katanga and Lena $+1{\cdot}2°$ to $+5{\cdot}8°$. The specific gravity of the surface-water in a broad channel along the coast never exceeded 1·023, in general only amounted to 1·01 or under. The latter figure corresponds to a mixture of about one part sea water with two parts river water. This shows indisputably that a warm surface current of little salinity from the mouths of the Obi and the Yenissei runs first along the coast towards the north-east, and then under the influence of the rotation of the earth in an easterly direction. Other similar currents originate from the Katanga, Anabor, Olonek, Lena, Jana, Indigirka, and Kolyma, all which pour their waters, more or less heated during the hot summer of Siberia, into the Polar Sea and render it, during a short period of the year, almost free of ice.

On the night between August 27 and 28 the *Vega* parted from the *Lena* off the mouth of the River Lena. There is scarcely any hope now that the voyage will be completed before next summer. No doubt the *Vega* has got into a safe winter-harbour, and that during the detention of the expedition a rich harvest of scientific results will be gathered.

THE FORMATION OF MOUNTAINS

PROF. ALPHONSE FAVRE, of Geneva, has been making an interesting series of experiments to illustrate the formation of the great inequalities of the earth's surface by means of lateral thrust or crushing. These he describes and illustrates in a recent number of *La Nature*, to which we are indebted for the illustrations which accompany this article. Prof. Favre refers to the early experiments of Sir James Hall with various kinds of cloth, which he made to assume a variety of shapes by means of weights. He speaks of the various theories of the elevation of mountains, and especially of that of H. B. de Saussure, whose term *refoulement* seems to have meant much the same as that used by M. Favre, *écrasement latéral*.

The three systems, M. Favre says, which account for the origin of mountains by forces which push the great mineral masses from below upwards, from above downwards, or laterally, do not differ so much from each other as at first sight appears. Those geologists who have admitted the system of elevations as the principal cause of modification of the surface of the globe, would probably enough admit the formation of depressions as a secondary modification; and so those who have accounted for these modifications mainly by depression, would probably enough also admit elevation as a secondary factor. Again, in the system of lateral crushing, there is a general depression of the surface of the earth, since there is a diminu-

tion in the length of the radius of our globe, and yet there result elevations of the ground in the midst of this general depression.

The cause of lateral crushing, M. Favre goes on to say, is owing to the cooling of the earth. It is, in fact, very probable that our globe is at the stage when, according to Élie de Beaumont, "the mean annual cooling of the mass exceeds that of the surface, and exceeds it more and more." It must follow that the external strata of the globe, tending always to rest on the internal parts, are wrinkled, folded, dislocated, depressed at certain points, and elevated at others.

"The experiments," M. Favre continues, "which I have made at the works of the Geneva Society for the manufacture of physical instruments, resemble much those of Sir James Hall; they differ notably, however, in two points:—1. The celebrated Scotchman caused the matter which he wished to compress to rest on a body which itself could not be compressed, while I placed the layer of clay employed in these experiments on a sheet of caoutchouc, tightly stretched, to which I made it adhere as much as possible; then I allowed the caoutchouc to resume its original dimensions. By its contraction the caoutchouc would act equally on all points of the lower part of the clay, and more or less on all the mass in the direction of the lateral thrust. 2. Hall compressed, by a weight, the upper surface of the body which he wished to wrinkle, which prevented any deformation, while by leaving that surface free, I have seen, during the experiment, forms appear similar to those of hills and mountains which may be observed in various countries."

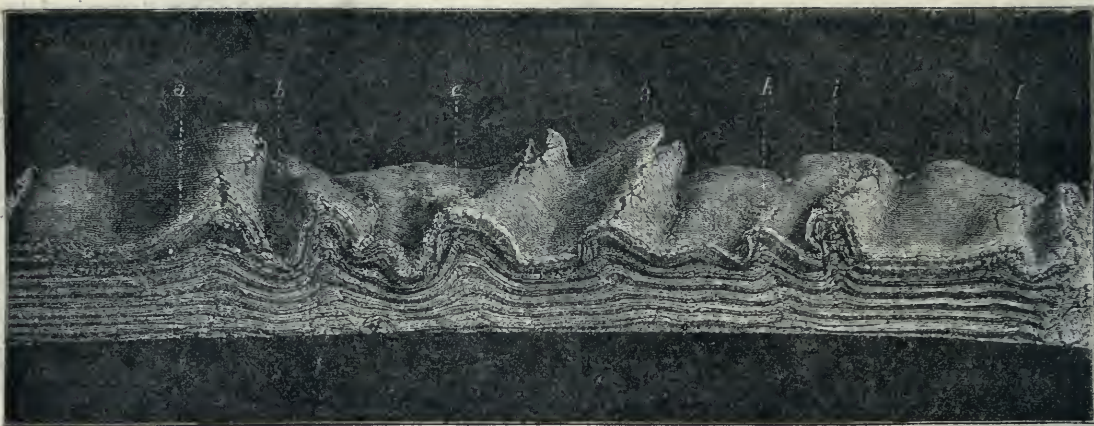

FIG. 1.

"The arrangement of the apparatus is very simple. A sheet of india-rubber 16 mm. in thickness, 12 cm. broad, and 40 cm. long, was stretched, in most of the experiments, to a length of 60 cm. This was covered with a layer of potter's clay in a pasty condition, the thickness of which varied, according to the experiments, from 25 to 60 mm. It will be seen from the dimensions indicated that pressure would diminish the length of the band of clay by one-third. This pressure has been exerted on certain mountains of Savoy. For example, the section which I have given [1] of the mountains situated between the Pointe-Percée and the neighbourhood of Bonneville enables it to be seen that those folded and contorted strata which are shown between Dessy and the Cal du Grand Barnaud cover a length which is two-thirds of that which they had before compression. These mountains, then, have been subjected, like the potter's clay, to a compression indicated by the ratio of 60 to 40. Contortions are not, perhaps, observed over all the surface of the globe; it has not been equally folded in all its extent, but they are found in a great number of countries, and even beneath strata almost horizontal. Sometimes the folds approach

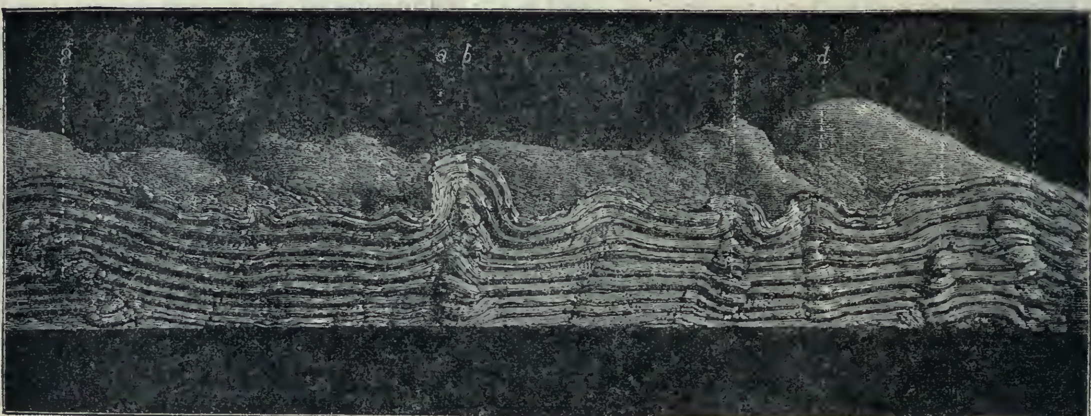

FIG. 2.

[1] *Bullet. Société Géologique de France*, 1875, t. iii. pl. xxii. A. Favre, *Recherches Géologiques*, Atlas, pl. ix.

the vertical, and are close against each other; this structure indicates that pressure has been exercised in a stronger manner than I have indicated.

"These powerful lateral thrusts of the external and solid parts of the globe appear to result from a diminution which the radius of the interior pasty or fluid nucleus has undergone during millions of ages. It may have been sufficiently great to cause the solid crust (which must always have been supported on the interior nucleus, whose volume continually diminishes) to assume the forms which we know, with a slowness equal to that of the contraction of the radius.

"To return to my experiments. At the extremities of the band of clay are pieces of wood or supports, which accompany it in its movement of contraction. The clay is thus compressed at once by its adhesion to the caoutchouc and by lateral pressure of the supports. By the influence of the caoutchouc alone, without the presence

Fig. 3.

of the supports, there are formed only slight wrinkles on the surface of a sheet of clay 3 or 4 ctm. in thickness; and if the supports alone compressed the clay placed on a material which is not compressed (a very smooth oiled plate), the clay scarcely wrinkles near the centre of its surface; it increases a little in thickness and forms swellings (*bourrelets*) against the supports. The strata which appear to divide the masses of clay, and which are represented in the figures, are not really strata, but simply horizontal lines at the surface of the clay.

Such pressure as has been applied in these experiments produces contortions of strata which elevate the surface of the matter compressed, as well in the plane parts or plains, as in those which take the forms of valleys, hills, or mountains. These latter have the appearance of vaults or folds, sometimes perpendicular, sometimes warped (*déjétes*); the ridges are complete.

Fig. 4.

or broken at the summit by a longitudinal fracture, narrow below and wide above; next, another fracture, narrow above and wide below, is produced at the base of the mountain or vault. The sides of valleys are sometimes almost vertical, sometimes present gentle slopes. The strata are less strongly contorted in the lower parts than in the neighbourhood of the upper surface. They are disjoined in certain parts by fissures or caverns; they are traversed by clefts or faults inclined or vertical. All these deformations are the more varied in that they are not similar on the opposite sides of the same band of clay.

Most of these phenomena are seen in Fig. 1, which represents the result of an experiment made on a band of clay, whose thickness, before compression, was about 25 mm., while after that it attained 62 mm. at the culminating point. At *a* is seen a vault a little broken at the summit, covering a cavern similar to that figured in

the memoir of Sir J. Hall (*Trans.* R. S. E., vol. vii. 1813), and to that of the Petit Bornand in Savoy (Favre, *Recherches*, pl. x.); at *b* is a valley open at one of its ends and almost closed at the other; at *e* is a vault almost straight, the prolongation of which is very level; at *g, h*, and *l* are vaults twisted and a little broken, while at *i* is a broken fold, the curves of which are almost vertical. All these accidents of the ground recall those which have been so often observed in the Jura, the Alps, and the Appalachians.

Fig. 2 represents a band of clay whose thickness was about 40 mm. before compression, and 65 after. We remark contortions similar to those of the preceding figure, among others a vault *a*, very exactly formed. At distances are seen vertical slices, on which the pressure appears to have acted in a particularly energetic fashion, and which may be called "zones de refoulement;" the strata are there broken in an exceptional manner, often separated from each other. One of these vaults is replaced by a single fault on the opposite side of the band of clay.

Before compression, in the band of clay in Fig. 3, were seen the two divisions which are seen there now—that in the right was 33 cm. long, and 25 mm. thick at *a*, and 35 at *b*; the left division was 25 cm. long, and 65 mm. thick. A gentle slope united the part *c* to the part *b*. After compression, the mean height of *ab* was 45, and that of *c* 75 mm. All the layers were spread horizontally.

In this experiment I have sought to imitate the effect of crushing at the limit of a mountain and a plain. The height of the mountain *c* has been notably increased, the five or six upper layers have advanced on the side of the plain; they encroach on it. The plain has, however, offered a resistance sufficiently great to cause the strata of the mountain to be strongly inflected at the bottom. From this struggle between the plain and the mountain, there resulted a cushion, *d*, which is the first hill at the foot of the height. It also resulted that the strata of the plain assumed an appearance of depression at contact with the mountain in consequence of the vault which is formed at *b*; they plunge underneath the mountain. This resembles what is often seen in the Alps at the junction of the first calcareous chain and the hills of "mollasse;" in fact, the strata of the latter rock seem to plunge under those of the neighbouring heights. In consequence of the pressure, there are formed several ranges of hills in the plain between *b* and *a*.

"In Fig. 4 the band of clay had, before compression, a thickness of 45 mm.; after that the culminating point was more than 10 cm. I have here sought to represent what must happen when terrestrial pressure is exerted on horizontal strata still moist, deposited at the bottom of a sea where are two mountains already solidified. For this purpose I placed in the caoutchouc and under the clay two bare cylinders of wood, *a* and *b*, of about 35 mm. radius, at 20 cm. from the ends of the band of clay, and at the same distance from each other. Before compression, the surface of the clay and the strata were completely horizontal. Pressure gave rise at the top of the half-cylinder, *a*, to a valley, *c*, formed by a twisting of the beds to the right, and by a little mountain, *d*, to the left. But I do not believe that it has ever been thought to assign to a valley an origin of this nature.

"On the other semi-cylinder, *b*, is produced an enormous elevation which has carried the ground to *e*, with such a rupture that the left lip, *f,g*, has suffered a complete reversal by turning, as on a hinge, around the horizontal line which passes by the point *h*. It follows that the four upper strata of clay designated by the figures 1, 2, 3, 4, being in a normal position before compression, are, after that, so arranged as to show the succession represented by the following arrangement of figures:—1, 2, 3, 4, 4, 3, 2, 1, 1, 2, 3, 4, making the section of this formation by a line drawn from *x* to *z*. If the left lip should disappear we should then have between the points *x* and *z* the section 1, 2, 3, 4, 5, 1, 2, 3, 4, 5. Sections analogous to these, presenting inversions in the order of strata, are known to geologists.

"The forms assumed by the clay depend on several circumstances which it is difficult to describe, such as the strength and the rate of compression, the thickness and the greater or less plasticity of the clay, &c. Why have accidents of the upper surface of the clay, which are intimately connected with those of the interior of the mass, so small an extension that they are not even similar in the two sides of a band of clay? This small continuity is owing to causes which we can neither foresee nor appreciate. Is it not the same in nature? Why is the chain of the Alps not a true chain, but a succession of masses often oblique with respect to each other? Why, in the Jura, do we see chains which have for their prolongation plains and valleys? It is always the case that the forms and structures obtained in these experiments have an incredible resemblance to those which are found on the surface of the globe. But it must be admitted that many of the latter have not been reproduced by these artificial crushings.

"It appears probable that, by pressures more powerful and more variedly employed, we might obtain again very different structures. But I have not thought it necessary to multiply these experiments, thinking that the varied forms which have resulted show sufficiently the effects of crushing."

GEORGE HENRY LEWES

THIS is a name which has been long before the reading public of England, and the announcement of Mr. Lewes's death, on Saturday last, at the age of sixty-one years, will be received by very many with genuine regret. This will be especially the case with those who have reached or passed middle life, for latterly Mr. Lewes's name has come little before the public, and what work he has done appeals to a comparatively small circle. Of Mr. Lewes's many-sidedness every one knows; he commenced his career as a novelist, and ended as a physiological psychologist—perhaps in some respects no very great leap, after all; indeed the two functions may be said to be combined in that greatest of philosophical novelists, if not of novelists absolutely, "George Eliot," Mr. Lewes's widow. Science owes a good deal to Mr. Lewes; for, though he made little or no pretension to be an original investigator in physical science, he did very much by his writings to give the general public an idea of what real science is, and to help forward the good work of carrying it into every-day life. His "Physiology of Common Life" had a long and deserved popularity, and even yet, we believe, is often "asked for" at libraries and book-shops. His "Biographical History of Philosophy" is thoroughly readable and full of information, which is more than can be said of philosophical works generally. Of his "Life of Goethe," one of the very few masterly biographies, we leave it to others to speak, though he did much there to bring out the real importance of Goethe's botanical and other scientific researches. Of his latest work, "Problems of Life and Mind," we spoke at length on the appearance of the volumes that have been published; in these volumes and in one or two letters and articles contributed to our pages, Mr. Lewes was perhaps at his best as an investigator in a department of science with which we are cautious of interfering, but which has a strange fascination for many thinkers. Altogether Mr. Lewes filled an important and many-sided place in the intellectual life of this country during his long career. It is easy to say that a man of his unusual keenness of mind might have achieved permanent greatness by concentrating his great store of energy in one

particular direction; but then he would not have been the innately versatile George Henry Lewes. His influence has been spread over a wide field, and has been largely beneficial to progress and enlightenment; he never aimed, we believe, at piling up an enduring monument to himself.

NOTES

MR. E. J. STONE, F.R.S., Astronomer-Royal at the Cape of Good Hope, has been appointed to the Radcliffe Observatory, Oxford, in place of the late Rev. R. Main.

MR. WILLIAM SPOTTISWOODE, having been elected President of the Royal Society on Saturday last, has resigned the office of Secretary to the Royal Institution. At the meeting, on Monday last, it was proposed that the Members of the Royal Institution subscribe to present a bust of Mr. Spottiswoode to the Institution as a recognition of his valuable services as Treasurer and Secretary successively.

WE have already referred to the new Parkes Museum of Hygiene, at University College, London, and we now earnestly draw our readers' attention to the appeal made by the Executive Committee for subscriptions towards an endowment, which is absolutely necessary for the efficiency of the institution, in diffusing the much needed knowledge of sanitary appliances and their uses. Although quite in its infancy, the Parkes Museum contains objects relating to life-protection, dietetics, clothing, furnishing, engineering, and architecture—in fact, every branch of hygiene. The library already consists of between 300 and 400 volumes, exclusive of pamphlets. "It cannot be too widely known," the Executive Committee state, "that it is intended to extend the benefits of the Museum to all classes, so that not only professional men, but owners of property, employers of labour, artisans, and others, both men and women, may be able to study at their leisure the subjects in which they are most interested." The Executive Committee, therefore, confidently appeal for pecuniary support to all those who, while being interested in technical education and sanitary science, have the inclination and the means to give such assistance. The Committee will not only be glad to receive subscriptions of money, but also books and pamphlets in any language, statistical tables, maps, plans, and other drawings, models, apparatus, or specimens illustrating any branch of hygiene. Subscriptions may be paid to the Treasurer, Mr. Berkeley Hill, 55, Wimpole Street, W. All communications relating to the presentation of articles to the Museum should be addressed to the Curator, Mr. Mark H. Judge, Parkes Museum, University College, Gower Street, W.C.

THE *Daily News'* New York correspondent telegraphs that Mr. Edison announces that he has perfected a machine for measuring the current used in the electric light. It consists of an apparatus placed in every house lighted by electricity, which registers the quantity of electricity consumed, and uses for the purpose the one-thousandth part of the quantity consumed in the building. Mr. Edison declares that his invention of the light, including the arrangement for counteracting loss in subdivision, is now completed. His experiments at present are directed to reducing the cost. He has, he says, already brought this decidedly below the cost of gas, and as soon as the minimum is reached, will make the results public. The *New York World* contains the following interesting details of Mr. Edison's doings:—"Dozens of workmen and machinists are hard at work at Menlo Park on the new buildings, the workshop being now almost ready for the roof. Mr. Edison said to a reporter for the *World*, 'I don't know when I am going to stop making improvements on the electric light. I've just got another one that I found by accident. I was experimenting with one of my burners when I dropped a screw-driver on to it. Instantly the light was almost doubled and continued to burn with the increased power. I examined the burner and found it had been knocked out of shape. I restored it to its original form, and the light was decreased. Now, I make all my burners in the form accidentally given to that one by the screw-driver. The result is that I can produce the amount of light given out by the first burner with little more than half the power. It is almost impossible to calculate with certainty the resources of my light, but I have engaged a mathematician to work out the problem from my data.' On the whole, Mr. Edison states he is confident of success, however much any one may be puzzled by his methods or claims."

THE Corporation of Liverpool have given notice that they intend to apply in the ensuing Session for an Act authorising the lighting of the public streets, places, and buildings within the borough by means of the electric light, "or otherwise than by means of gas." The Corporations of Warrington, Derby, South Shields, Leicester, Blackburn, Over Darwen, and Stratford-upon-Avon, in conjunction, in the latter borough, with the Local Board of Health, ask for similar powers in the Bills which they intend to promote.

THE sixth part of the illustrated work of C. J. Maynard on the "Birds of Florida, and the Water and Game Birds of Eastern North America," has just been published, and contains three quarto plates, one of them representing sixty-six pecies of eggs.

MESSRS. MACMILLAN AND CO. will shortly publish "Notes of a Naturalist on Board the *Challenger*," by Mr. H. N. Moseley, F.R.S., who was on the scientific staff of the expedition. The work will be illustrated.

THE zoological station of the Zoological Society of the Netherlands has published its third report. During the summer of 1878 the station was erected on the Island of Terschelling, and in the course of two months it was visited by ten zoologists. This year the investigation of the Zuider-Zee was the principal object kept in view, and for that purpose some fourteen dredging excursions with the boat stationed in West-Terschelling for laying buoys were organised. The station underwent no small improvement, a nicely-organised aquarium-room being added to the main building. Here a small hot-air engine of about $\frac{1}{10}$-horse power (construction of D. W. van Rennes, Utrecht) drives an air-forcing pump; the compressed air gathered in a white-iron box is distributed through numerous aquarium-vessels by means of gum-elastic tubes and small glass-canules. By means of this arrangement even on hot days numerous animals were kept alive. The investigation of the Zuider-Zee not being brought to a close, the Island of Terschelling will probably next year see the station again erected in one of its picturesque valleys.

AT last week's meeting of the Paris Academy M. Pasteur read a critical examination of the posthumous papers of Claude Bernard, in which statements were made opposed to the conclusions reached by M. Pasteur. He regards the manuscript of Bernard as a sterile attempt to substitute for well-established facts the deductions of an ephemeral system. "The errors, however," M. Pasteur says, "of those who in the sciences have accomplished a valiant career have only the philosophical interest which attaches to the knowledge of our human frailty."

THE following are the probable arrangements of the Royal Institution for the Friday Evening Meetings before Easter, 1879:—January 17, Prof. Tyndall, "The Electric Light;" January 24, Prof. W. E. Ayrton, "The Mirror of Japan and its Magic Quality;" January 31, Mr. H. Heathcote Statham,

"The Logic of Architectural Design;" February 7, Rev. H. R. Haweis, "Bells;" February 14, Prof. G. Johnstone Stoney, "The Story of the November Meteors;" February 21, Prof. Roscoe, "A New Chemical Industry;" February 28, Sir Wm. Thomson, "The Sorting Demon of Maxwell;" March 7, Prof. Huxley, LL.D., F.R.S.; March 14, Mr. E. B. Tylor, "The History of Games;" March 21, Prof. Abel, C.B., F.R.S., "Recent Contributions to the History of Detonating Agents;" March 28, Sir Henry C. Rawlinson, K.C.B., D.C.L., "The Geography of the Oxus, and the Changes of its Course at different Periods of History;" April 4, Mr. Warren de la Rue, D.C.L., F.R.S.

The Smithsonian Institution of Washington, U.S., has issued a catalogue of their valuable publications, and a list of various societies, journals, &c., with which they exchange publications. The Institution is anxious to add to this list any societies with which they have not hitherto been in communication, and also the names of specialists in all parts of the world. Communications should be addressed to Dr. Spencer F. Baird, at the Institution.

The Rev. S. J. Whitmee writes us with reference to reports which have lately reached this country of violent volcanic eruptions in the Society Islands, and also in the neighbourhood of New Britain. "These," he says, "have not, however, been confirmed, and from private information received from Tahiti, I hear that nothing has occurred in the Society Islands like what has been reported. From an Australian paper I saw a month ago, that the master of the brigantine *Matautu* had found a vast quantity of pumice-stone about the Ellice Islands. This is now confirmed by the captain of the missionary barque *John Williams*, who visited these islands in May and June last. From his account, a brief notice of which appeared in the *Times* last Friday, we learn that the pumice has reached the Ellice group from another locality, and that there has been no eruption in those islands. I give the following quotation from a notice of the *John Williams*' voyage which appears in the *Samoa Times* for July 27:—'In the Gilbert group, although the currents were somewhat irregular, the old strong easterly set seems to prevail again. In fact, sometimes it was running at the rate of thirty-six to forty-eight knots in the twenty-four hours. . . . On the outward voyage (from Samoa), when about 120 miles to the east of Nukulaelae, vast quantities of pumice-stone were passed, and the shores of all the Ellice Islands from Nukulaelae to Nintao and Nanumea are thickly covered with it. It is no exaggeration to say that hundreds of tons have been thrown up on every island. Stumps of trees and thick bamboos with roots attached have been thrown up on some of the islands. Early in May the brig *Isabella*, Everts, master, from Sydney, called at Vaitupu, and there left a report that there had been some volcanic eruption in the Society group. One report even says that Raiatea and Borabora have been destroyed, and 2,000 lives lost. There were also passed while beating back (to Samoa) between Nukulaelae and Fakaofo, one *mālili* tree about eighty feet long, one cocoa-nut tree, and four other gigantic forest trees, all evidently proofs that the story of Capt. Evers is probably only too true. The pumice-stone began to arrive on the Ellice Islands about the middle of April, and continued till the middle of June. When first noticed there was no seaweed growth on the pieces, and no barnacles, but by the beginning of June this began to be plainly noticeable. There is no trace of the pumice-stone in the Union or Gilbert Groups, and the time of its arrival in the Ellice group will be interesting to those who study the question of ocean currents.' From the above remarks it would appear that the pumice is supposed to have arrived from the east, and it is taken for granted that it has come from the Society Islands. But it is at least doubtful whether any eruption has taken place there. And, at a date later than that given as the time when the pumice ceased to reach Vaitupu, the *John Williams* met with trees far to the east of that island. If it had come from the east, surely some would have been seen also about the Union or Tokelau Islands. We must wait for further information as to where the eruption took place; but I am inclined to think it must have been to the west of the Ellice Islands."

We hear that M. Mannheim is engaged upon the preparation of a work entitled "Géométrie Cinématique." Hitherto our acquaintance with this important subject has been derived from Italian and German works, or these translated into French. M. Mannheim's ability as a geometer leads us to expect he will produce an elegant treatise on this branch of geometry.

According to the report for 1877 recently issued, made by Dr. Corfield, the Medical Officer of Health for St. George's, the death-rate for the parish in that year was as low as 17·46. Of the three sub-districts into which the parish is divided Hanover Square had a rate of 16·58, Mayfair of 13·04, and Belgravia of 18·70. The rate for the whole parish (17·46), with a calculated population of 91,037 is compared with some of the twenty-two "other large towns of the United Kingdom." Portsmouth has the lowest rate (17·4), which is therefore just under, Brighton with 18·7 coming next. No foreign town has so low a death rate as St. George's parish, the nearest known approach being Philadelphia (18·8). Dr. Corfield has calculated the mean duration of life in the parish and in each of the sub-districts for 1877. For the whole parish it was 49·52 years, for Hanover Square sub-district 56·63, for Mayfair 62·66, and for Belgravia 45·53. The mean duration in the 22 towns on which the Registrar-General reports was (including London) 34·2.

Prof. E. Morren's useful "Correspondance Botanique" is continually increasing in size. This year it occupies 150 pages, against 92 last year. The principal increase is in the American department, which is much fuller and more complete than it has been before. But in Europe also there is an increase in the number of names, partly due no doubt to more accurate information, but partly also, we may hope, to an actual increase in the number of workers in botanical science. It is a significant fact that while second and third class university towns in Germany or Italy number their six or eight working botanists, mostly attached to the university, the number of names given under the heads of Oxford and Cambridge together is five.

The *Golos* publishes the following telegram from Tiflis, dated November 27:—"Telegraphic intelligence received to-day states that this morning at two o'clock a severe earthquake was experienced at Suram and Borjom. A frightful rumbling noise was heard during the earthquake, accompanied by a shock so severe that people were thrown from their beds. Nothing similar has occurred in the district before."

Yesterday M. Bardoux, Minister of Public Instruction, laid the first stone of the new practical school of the Faculty of Medicine in Paris.

The Commission for the reception of the great reflector at the Paris Observatory have assented to its reception, although the mirror cannot be used in its full breadth without being diaphragmised at the circumference. It is stated, moreover, that the instrument can be used only on a very few days in the year in the atmosphere of Paris, and that reflectors are decidedly unmanageable except under special circumstances. It remains to be explained, then, how Lord Rosse and the great Herschel could manage to make so many interesting discoveries with instruments declared so unsuitable for celestial observations.

The Paris Observatory being no more intrusted with the care of publishing the *International Bulletin of Meteorology*, which has been taken over to the rue de Grenelle by the Central

Bureau, the Paris Press are deprived of all the documents for current meteorology which were put at their disposition by M. Leverrier.

We are informed that Admiral Mouchez has signed with M. Martin the contract for the polishing of the great lens of the great refracting telescope prepared by M. Leverrier. The lamp, of 75 centimetres diameter, has been placed in the hands of M. Feil, the glass founder, to repair a few defects which have been detected. This operation is done by cutting out the defective parts and heating the glass to a state of liquidity. This process is sometimes used for central parts with success. Guinault, the originator of the process used now for glass-founding, is said to have so mended eighteen times one of the most celebrated glasses produced by him at the end of the last century.

We regret to announce the death of Dr. Eugen von Gorup Besanez, Professor of Chemistry at Erlangen University, and author of an excellent chemical handbook in three volumes. He had attained the age of sixty-two years.

Bentley and Trimen's "Medicinal Plants" has now reached its thirty-fifth number, and maintains in every way the excellent promise with which it started. Both the letterpress and the illustrations are of sterling quality, and the work, when completed, will be a complete repertorium for the botanico-medical student.

Near the Rhinefall at Schaffhausen a cave has been discovered which was evidently used as a dwelling-place in prehistoric times. Flints, broken jars, and bone rests were found in it. The jars were partly of Celtic and Roman origin.

We have on our table the following works:—"Six Months in Ascension," by Mrs. Gill, John Murray; "Robert Dick, Geologist and Botanist," by Dr. Smiles, John Murray; "Pocket Book for Chemists," by Thomas Bayley, E. and F. H. Spon; "The Mollusca of the Firth of Clyde," by Alf. Brown, Hugh Hopkins; "A Visit to South America," by Edwin Clark, Dean and Son; "Coal: its History and Uses," Edited by Prof. Thorpe, F.R.S., Macmillan and Co.; "Bau des Eozoon Canadense," by Karl Möbius, Theodore Fischer; "Flowers, and their Unbidden Guests," Translated by W. Ogle, Kegan Paul; "Vogelbilder aus fernen Zonen," by Dr. Ant. Reichenon, Theodore Fischer; "Dictionary of Scientific Terms," by William Rossiter, W. Collins and Sons; "On Foot in Spain," by J. S. Campion, Chapman and Hall; "Elementary Geometry Books," i.–v., Fourth Edition, by J. M. Wilson, Macmillan and Co.; "Treatise on Chemistry," vol. ii., part 1, by Professors Roscoe and Schorlemmer, Macmillan and Co.; "The Magic Lantern Manual," by W. J. Chadwick, F. Warne and Co.; "The Localisation of Cerebral Disease," by Dr. Ferrier, Smith, Elder, and Co.; "Cassell's Natural History," vol. ii., Edited by P. Martin Duncan, F.R.S., Cassell, Petter, and Galpin.

The additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Dr. Whately, R.N.; a Brazilian Tree Porcupine (*Sphingurus prehensilis*) from Trinidad, presented by Dr. J. F. Chittenden, jun.; a Common Peafowl (*Pavo cristatus*) from India, presented by Mrs. Russ; two Common Cormorants (*Phalacrocorax carbo*), British, presented by Mr. Frank Buckland, F.Z.S.; a Water Rail (*Rallus aquaticus*), British, presented by Mr. W. Thompson; a Black Lemur (*Lemur macaco*) from Madagascar, a Rufous-vented Guan (*Penelope cristata*) from Central America, purchased; a Red Kangaroo (*Macropus rufus*), born in the Gardens.

ROYAL SOCIETY—THE PRESIDENT'S ANNIVERSARY ADDRESS[1]

Gentlemen,

At the conclusion of this, the fifth and last year during which I shall have held the most honourable office of your president, I have the gratifying assurance that the communications made to the Society and its publications have in no respect fallen off in scientific interest and value. We have not, indeed, been called upon to undertake during the past year such responsible and time-absorbing duties in behalf of the Government as the Polar, Circumnavigation, Transit of Venus, and other Committees demanded of us during the previous four years; but some of the results already achieved by those expeditions have been contributed to our publications, and we are in expectation of more. It is also with satisfaction that I can refer to the good attendance at our evening meetings, *soirées*, and *réunions*, as evidence of the interest taken in our proceedings by the Fellows generally and their friends.

Before proceeding to touch upon some of the advances made in science during the last few years, I have, as heretofore, to inform you of the Society's condition and prospects, and of those duties undertaken by its Council, for information as to which non-resident Fellows look to the annual address.

The loss by death of Fellows, twenty-one in number, is but little short of last year's rate, while that of Foreign Fellows (six) is twice as great as last year. On the home list is Sir George Back, the last, with the exception of our late venerable President, Sir E. Sabine, of that celebrated band of Arctic voyagers which during the early part of the century added so much to our renown as navigators and discoverers. Sir George was further the companion of Franklin and Richardson in that overland journey to the American Polar Sea, in which human endurance was tried to the uttermost compatible with human existence, and the modest but thrilling narrative of which, by the first-named officers, will ever hold a unique place in the annals of scientific discovery. Of Indian explorers no less than four have been taken away, namely, Col. Sir Andrew Waugh, for many years Director of the Great Trigonometrical Survey of India; and shortly afterwards his successor, Col. Montgomerie; Dr. Oldham, for a quarter of a century the Director of the Geological Society of India; and Dr. Thomas Thomson, my fellow-traveller in the Himalaya, the narrative of whose explorations in Western Tibet contains the first connected account of the physical and natural features of that remote and difficult country. Lieut.-Gen. Cameron survived but for one year our late Fellow, Sir Henry James, his predecessor in the Direction of the Ordnance Survey of Great Britain. In the Rev. James Booth we have lost a mathematician of high attainments, and the author of many contributions to our own and other scientific journals. The Rev. W. B. Clark, of New South Wales, wrote many papers abounding in excellent observations on Meteorology and Geology, especially made in England, the Cape of Good Hope, Australia, and the Pacific. The Rev. R. Main, the Director of the Radcliffe Observatory, at Oxford, was a very eminent astronomer, and for nearly half a century an indefatigable author. Lastly, Earl Russell, the distinguished statesman and the earnest advocate, whether in the Government or in Parliament, of every measure for the promotion of scientific inquiry.

Of Foreign Fellows our losses are a great chemist in Becquerel, of Paris, whose election took place upwards of forty years ago; a great physiologist in Claude Bernard, also of Paris; the father of mycology, and for long the patriarch of Scandinavian botanists, Elias Fries; a most distinguished physicist and the recipient of both a Rumford and Copley medal in Regnault; a veteran anatomist in Weber; and in Secchi, of Rome, an astronomer of astonishing activity, the author of more than three hundred separate contributions to the science of which he was so great an ornament.

In matters of finance I may with satisfaction refer you to our treasurer's balance-sheets.

It will be in your recollection that Mr. T. J. Phillips Jodrell placed in 1874 a sum of 6,000*l.* at the disposal of the Society, with the view of its being devoted to the encouragement of scientific research by periodical grants to investigators whom your Council might think it expedient thus to aid. Shortly after the receipt of this munificent gift, the Government announced its

[1] Address of Sir Joseph Hooker, C.B., K.C.S.I., the President, delivered at the Anniversary Meeting of the Royal Society, on Saturday, November 30, 1878.

intention of devoting annually for five years 4,000*l.* to the same object, thus anticipating the special purpose which Mr. Jodrell had in view. Thereupon, with that gentleman's consent, his donation was temporarily funded, and the proceeds applied to the general purposes of the Society until some other scheme for its appropriation shall be approved. In April last I received a further communication from Mr. Jodrell, declaring it to be his wish and intention that, subject to any appropriation of the sum which we might, with the approval of the Society, make during his lifetime, it should immediately on his death be incorporated with the Donation Fund, the annual income in the meantime going to the general revenue of the Society. Upon this subject I have now to state that since the receipt of that letter Mr. Jodrell has approved of 1,000*l.* of the sum being contributed to a fund presently to be mentioned.

I have also to inform you of a check for 1,000*l.* having been placed in my hands by our Fellow, Mr. James Young, of Kelly, to be expended in the interests of the Society in such manner as I should approve.

Mr. De La Rue, to whose beautiful experiments I shall have occasion to refer, has presented to the Society both the letterpress and the exquisitely engraved facsimiles of the electric discharges described in his and Dr. Hugo Müller's paper, and which have appeared with that paper in the *Transactions*.

Our Fellow, Dr. Bigsby, has presented seven copies of his "Thesaurus Devonico-carboniferus" for distribution, and they have been distributed accordingly.

A very valuable addition to our gallery of deceased eminent Fellows has been the gift, by Mr. Leonard Lyell, of a copy in marble, by Theed, of the bust of his uncle, the late Sir Charles Lyell, F.R.S., together with a pedestal. This is the best likeness of the late eminent geologist that has been executed, and is in every respect a satisfactory one.

I have the gratification of announcing to you, that through the munificence of a limited number of Fellows, means have been advanced for reducing the fees to which all ordinary Fellows in future elected will be liable. That these fees, though not higher than the most economical expenditure on the part of the Society for its special purposes demanded, were higher than it was expedient to maintain if any possible means for reducing them could be obtained, was not only my own opinion but that of many Fellows. They exceed considerably those of any other scientific society in England or abroad; their amount has occasionally prevented men of great merit from having their names brought forward as candidates, and they press heavily, especially upon those who, with limited incomes, have other scientific societies to subscribe to. Nor does it appear to me as otherwise than regrettable that so high an honour as Fellowship of the Royal Society, the only one of the kind in England that is limited as to the number annually elected, and selective in principle, should be attainable only at a heavy pecuniary expenditure. It is true that our Fellows receive in return annually volumes of publications of great value to science generally; but these treat of so many branches of knowledge that it is but a fraction of each that can materially benefit the recipient, while their bulk entails an additional expenditure; and now that the individual papers published in the *Transactions* are separately obtainable, the advantages of Fellowship are less than they were when to obtain a treatise on his own subject a specialist had either to join the Society, or to purchase a whole volume or a large part of it annually.

It was not, however, till I had satisfied myself that the annual income of the Society, though not ample, was sufficient for its ordinary purposes, that its prospects in other points of view were good, and that the expenditure upon publication was the main, if not the sole, obstacle to a reduction of fees, that I consulted your treasurer on the subject of taking steps to attain this object.

My first idea was to create, by contributions of small amount, a fund, the interest of which should be allowed to accumulate; and when the income of the accumulated capital reached a sufficient amount to enable the Society to take the step without loss of income, to reduce either the entrance fee or annual contribution; and to which fund Mr. Young's gift should be regarded as the first donation.

This proposal was in so far entertained by your Council that they resolved to establish a Publication Fund, and to place Mr. Young's gift to the credit thereof; and further, appointed a committee to consider and report upon the Statutes of the Society concerning the fees.

The movement, once set on foot, met with an unexpectedly enthusiastic reception; several Fellows, with the best means of forming a judgment, not only approved of it, but offered liberal aid, urging that the reduction of fees should be the first and immediate object, and that, if such a course were thought desirable, the means of carrying it out would surely be forthcoming. On this your Treasurer prepared for my consideration a plan for raising 10,000*l.*, the sum required for effecting any material reduction; and we resolved to ascertain by private inquiry whether so large an amount could be obtained.

Here again our inquiries were responded to in a spirit of, I may say, unexampled liberality: in a few weeks upwards of 8,000*l.* was given or promised by twenty Fellows of the Society, and I need hardly add that the remaining 2,000*l.* was contributed very shortly afterwards.

At a subsequent meeting of the Council it was resolved:—

1.—That the sums referred to as the Publication Fund, as well as those received or that may be hereafter received, for the purpose of relieving future ordinary Fellows from the Entrance Fee, and for reducing their Annual Contribution, be formed into one fund.

2.—That the Entrance Fee for ordinary Fellows be henceforth abolished; and that the Annual Contribution for ordinary Fellows hereafter elected be three pounds (3*l.*). Also, that the income of the Fund above-mentioned be applied, so far as is requisite, to make up the loss to the Society arising from these remissions and reductions.

3.—That the account of this Fund be kept separate; and that the annual surplus of income, after providing for the remission and reduction above recommended, be re-invested, until the income from the Fund reaches 600*l.* So soon as the annual income reaches this amount, any surplus of income in any year, after providing for the remission and reduction above-mentioned, shall be available, in the first instance, in aid of publication and for the promotion of research.

A list of subscribers to this Fund will be placed in the hands or every Fellow, with the information that it will be kept open for future contributions, in the interests of research and of the Society's publications. I hope that it will be largely and speedily augmented, and that it may eventually reach an amount which will provide us with the means of accomplishing as much as is effected by the Government Fund, upon our own sole and undivided responsibility. I must not conclude my notice of this movement without a mention of those whose encouragement and liberality have most largely promoted it; and first of all, Mr. Spottiswoode, to whose counsel and active co-operation throughout, its success is mainly due; Messrs. Young's and Jodrell's contributions have already been alluded to, they have been supported by others:—2,000*l.* from Sir Joseph Whitworth, 1,000*l.* from Sir W. Armstrong, and 500*l.* each from His Grace the Duke of Devonshire, Mr. De La Rue, Messrs. Spottiswoode and Eyre, Dr. Siemens, and the Earl of Derby, and 250*l.* from Dr. Gladstone. The balance is the joint contributions of thirty-two Fellows.

I have to mention your obligations to Dr. W. Farr for the labour he has bestowed on ascertaining these vital and other statistics of the Society, upon an accurate knowledge of which the calculations for the reduction of fees had to be based; and to Mr. Bramwell for constructing a table showing to what extent the above changes will affect the Society's present and future income. It may interest you to know that the contributions of ordinary Fellows in future to be elected, is but little over that which was required of all Fellows from the very commencement of the Society's existence, namely, 1*s.* per week, and that the last Fellow who paid that sum died in 1869. So recent (1823) has been the augmented scale of payment in force up to the present date.

Looking back over the five years during which I have occupied this chair I recognise advances in scientific discovery and research at home and abroad far greater than any previous semi-decade can show. I do not here allude to such inventions as the telephone, phonograph, and microphone, wonderful as they are, and promising immediate results of great importance to the community, nor even to those outcomes of great research and high attainments, the harmonic analyser of Sir W. Thomson, the radiometer and otheoscope of Crookes, the bathometer and gravitation meter of Siemens, but to those discoveries and advances which appeal to the seeker of knowledge for its own sake, whether as developing principles, suggesting new fields of

research, or awakening attention to hitherto unseen or unrecognised, or unexplained phenomena of nature.

In the foremost rank as regards the magnitude of the undertakings and the combination of means to carry them out, nothing in the history of physical science can compare with the Transit of Venus Expeditions. To observe the transit of Venus various nations of Europe and the United States competed as to the completeness of the expeditions they severally equipped. The value[1] of the solar parallax cannot be ascertained until the results of all the expeditions are taken into account, when it will have an international claim to acceptance. But advances in this direction will not have ended here, the very difficulties attending the observation of the transit of Venus, having directed attention to the method originally suggested by the Astronomer-Royal in 1857, of obtaining the solar parallax from the diurnal parallax of Mars at its opposition.

Mr. Gill, by the skilful employment at Ascension Island of the heliometer lent by Lord Lindsay, has greatly increased the accuracy of the method by which the necessary star comparisons with Mars are made, and there is every reason to believe that the results of his observations, which are now in course of reduction, will be very satisfactory.

Within the last two years a remarkable addition has been made to the number of members of the solar system by Prof. Asaph Hall's discovery of the satellites of Mars; and more recently, during the solar eclipse which was visible in America, by Prof. Watson's detection of planetary bodies within the orbit of mercury.

In 1876 Schmidt recorded an outburst of light in a star in Cygnus, which showed a continuous spectrum containing bright lines similar to those of the remarkable star of 1866. As the star waned the continuous spectrum and bright lines faded, all but one bright line in the green, giving the object the spectroscopic appearance of a small gaseous nebula.

Great progress has been made during the last five years at Greenwich in the method of determining the motions of the heavenly bodies by the displacement of the lines in their spectra, as first successfully accomplished by Mr. Huggins in 1868. Not only do the results obtained by the stars observed at Greenwich agree with those of Mr. Huggins, as satisfactorily as can be expected in so delicate an investigation, but the motions of seventeen more have been determined; whilst the trustworthiness of the method has been shown by the agreement of the values for the rotation of the sun and the motions of Venus, with the known movements of these bodies. Mr. Huggins has also obtained photographs of the spectra of some of the brighter stars, which give well-defined lines in the violet and ultra-violet parts of the spectrum. These spectra have already shown alterations in the lines common to them and the sun, which are of much interest.

In solar physics, which afford remarkable evidence of Mr. Lockyer's energetic labours in this country and Mr. Janssen's in France, I must mention our Foreign Member's wonderful photographs of the sun, wherein the minutest of the constant changes in the granulations exhibited on its surface (and which vary in size from $\frac{1}{10}$ of a second to 3 or 4 seconds) can be studied in the future from hour to hour and day to day; as can also their different behaviour at different periods of frequency of sunspots.

Before dismissing this fruitful field of research, I must allude to Mr. Lockyer's discovery of carbon in the sun; and to his announced but not yet published observations on the changes and modifications of spectra under different conditions, some of which he even regards as indicating the breaking up of the atoms of bodies hitherto regarded as elementary.

Some important investigations on the electric discharge have been communicated to the Society by Messrs. De La Rue and Müller, and by Mr. Spottiswoode. These, prosecuted by different means, tend to limit the possible causes of the stratification observed in discharges through vacuum tubes. They also point to the conclusion that this phenomenon is in a great measure due to motions among the molecules of the residual gas, which themselves become vehicles for the transmission of electricity through the tube. It is well known that gases at atmospheric pressure offer great resistance to the passage of electricity; and that this resistance diminishes (to a certain limit, different for different gases) with the pressure. And the researches in question appear to show that the discharge, manifestly disruptive at the higher pressures, is really also disruptive even at pressures when stratification takes place. The period of these discontinuous discharges has not yet been the subject of measurement, but it must, in any case, be of a very high order.

Under the auspices of the Elder Brethren of the Trinity House, and as their scientific adviser, Prof. Tyndall has conducted an investigation on the acoustic properties of the atmosphere. The instruments employed included steam whistles, trumpets, steam syrens, and guns. The propagation of sound through fog was proved to depend not upon the suspended aqueous particles, but upon the condition of the sustaining air. And as air of great homogeneity is the usual associate of fog, such a medium is often astonishingly transparent to sound. Hail, rain, snow, and ordinary misty weather, were also proved to offer no sensible obstruction to the passage of sound. Every phenomenon observed upon the large scale was afterwards reproduced experimentally. Clouds, fumes, and artificial showers of rain, hail, and snow were proved quite ineffectual to stop the sound, so long as the air was homogeneous, while the introduction of a couple of burners into a space filled with acoustically transparent air soon rendered it impervious to the waves of sound. As long as the continuity of the air in their interstices was preserved, the sound-waves passed freely through silk, flannel, green baize, even through masses of hard felt half an inch in thickness, the same sound-waves being intercepted by goldbeater's skin. A cambric handkerchief which, when dry, offered no impediment to their passage, when dipped into water became an impassable barrier to the sound-waves.

Echoes of extraordinary intensity were sent back from non-homogeneous transparent air; while similar echoes were afterwards obtained from the air of the laboratory, rendered non-homogeneous by artificial means. Detached masses of non-homogeneous air often drift through the atmosphere, as clouds pass over the face of the sky. This has been proved by the fluctuations observed with bells having their clappers adjusted mechanically, so as to give a uniform stroke. The fluctuations occur only on certain days; they occur when care has been taken to perfectly damp the bell between every two succeeding strokes; and they also occur when the direction of the sound is at right angles to that of the wind. Numerous observations were also made on the influence of the wind, the results obtained by previous observers being thereby confirmed. From his own observations, as well as from the antecedent ones of Mr. Alexander Beazeley and Prof. Osborne Reynolds, Prof. Tyndall concludes that the explanation of this phenomenon given by Prof. Stokes is the true one.

Turning now to biological branches of science, I find that the discoveries and researches of the past five years in this department also are far in advance of those of any previous period of equal length. The *Challenger* Expedition was, in point of the magnitude of the undertaking and completeness of its equipment, the rival of that for observing the Transit of Venus. Its general results, as far as hitherto made known, have been dwelt upon at length in my previous addresses, and the publication of them in detail is being rapidly pushed forward. Some very important papers by Mr. Moseley on the corals collected on the voyage have indeed been published in our *Transactions* with admirable illustrations by himself.

To the botanist and geologist no subject has a greater interest than that of the conditions under which the successive floras, which inhabited the polar area, existed and were successively dispersed over lower latitudes previous to their extinction, some *in toto* and over the whole globe, whilst others, though extinct in the regions where they once flourished, exist now only in lower latitudes under identical or under representative forms. It is only during the last few years that, thanks to the labours of those engaged in systematic botany in tracing accurately the directions of migrations of existing genera and species, and in determining the affinities of the extinct ones, and of palæontologists in referring the latter to their respective geological horizons, that any material advance has been made towards a knowledge of the origin and distribution of earlier and later Floras. I cannot better illustrate the condition of this inquiry than by calling your attention to two most recent publications on the subject, which have both appeared within the last few months.

[1] The Astronomer-Royal informs me that Capt. Tupman, who has taken the principal share in the superintendence of the calculation, fixes provisionally on a mean parallax of 8″·8455, corresponding to a distance of 92,400,000 British miles, but that the observations would be fairly satisfied by any parallax between 8″·82 and 8″·88, which in distance produces a range of from 92,044,000 and 92,770,000 miles, differing by 726,000 miles, a quantity almost equal to the sun's diameter.

As a contribution to the principles of geographical botany, Comte Gaston de Saporta's essay, entitled "L'Ancienne Végétation Polaire" (which appeared in the *Comptes Rendus* of the French International Geographical Congress) is a very suggestive one, and, having regard especially to its author's eminence as a geologist and palæontologist, is sure to command attentive study. Although it may be argued that neither solar nor terrestrial physics, nor geology, nor palæontology are in a sufficiently advanced condition to warrant the acceptation as altogether established truths of all conclusions advanced in it, still the array of facts adduced in evidence of these conclusions is very imposing, while the ability and adroitness with which they are brought to bear on the subject are almost worthy of the great French genius whose speculations from the starting-point of the theory, which is that life appeared first in the northern circumpolar area of the globe, and that this was the birthplace of the first and of all subsequent floras.

I should premise that Count Saporta professedly bases his speculations upon the labours of his friend, Professor Heer, whose reasonings and speculations he ever puts forward with generous appreciation, while differing from him wholly on the subject of evolution, of which he is an uncomprising supporter, Professor Heer holding to the doctrine of the sporadic creation of species.

In his "Epoques de la Nature" Buffon argues that the cooling of the globe, having been a gradual process, the polar regions must have been the first in which the heat was sufficiently moderate for life to have appeared upon it; that other regions being as yet too hot to give origin to organised beings, a long period must have elapsed, during which the northern regions, being no longer incandescent, as they and all others originally were, must have had the same temperature as the most tropical regions now possess.

Starting from this thesis, Count Saporta proceeds to assume that the termination of the azoic period coincided with a cooling of the water to the point at which the coagulation of albumen does not take place; and that then organic life appeared, not in contact with the atmosphere, but in the water itself. Not only does he regard life as originating, if not at the North Pole, at least near to it, but he holds that for a long period life was active and reproductive only there. In evidence of this he cites various geological facts, as that the older, and at the same time the richest, fossiliferous beds are found in the cool latitudes of the North, namely in lats. 50° to 60°, and beyond them. It is in the North, he says, that Silurian formations occur, and though they extend as far south as lat. 35° N. in Spain and America, the most characteristic beds are found in Bohemia, England, Scandinavia, and the United States. The Laurentian rocks again, he says, reach their highest development in Canada, and palæozoic rocks cover a considerable polar area north of the American great lakes, and appear in the coasts of Baffin's Bay, and in parts of Greenland and Spitzbergen. It is the same with the Upper Devonian and marine carboniferous beds preceding the coal formations; these extend to 76° N. in the polar islands and in Greenland, and to 79° N. in Spitzbergen, and he adds that M. d'Archiac has long ago remarked that, though so continuous to the northward, the coal-beds become exceptional to the southward of 35° N. Hence Count Saporta concludes that the climatic conditions favourable to the formation of coal were not everywhere prevalent on the globe, for that while the southern limit of this formation may be approximately drawn, its northern must have extended to the Pole itself.

I pass over Saporta's speculations regarding the initial conditions of terrestrial life, which followed upon the emergence of the earlier stratified rocks from the Polar Ocean, and proceed to his discussion of the climate of the carboniferous epoch as indicated by the characters of its vegetation, and of the conditions under which alone he conceives this can have flourished in latitudes now continuously deprived of solar light throughout many months of the year. In the first place, he accepts Heer's conclusions (founded on the presence of a tree-fern in the coal measures specifically similar to an existing tropical one), that the climate was warm, moist, and equable, and continuously so over the whole globe, without distinction of latitude. This leads him to ask whether, when the polar regions were inhabited by the same species as Europe itself, they could have been exposed to conditions which turned their summers into a day of many months' duration, and their winters into a night of proportional length?

A temperature so equable throughout the year as to favour a rich growth of cryptogamic plants, appears, he says, to be at first sight incompatible with such alternating conditions (as a winter of one long night and a summer of one long day); but equability, even in high latitudes, may be produced by the effect of fogs due to southerly warm oceanic currents, such as bathe the Orkneys and even Bear Island (in lat. 75° N.), and render their summers cool and winters mild. To the direct effects of these he would add the action of such fogs in preventing terrestrial radiation, and hence the cold this produces; and he would further efface the existing conditions of a long winter darkness by the hypothesis that the solar light was not, during the formation of the coal, distributed over the globe as it now is, but was far more diffusive, the solar body not having yet arrived at its present state of condensation.

That the polar area was the centre of origination for the successive phases of vegetation that have appeared in the globe is evidenced, under Count Saporta's view, by the fact that all formations, carboniferous, jurassic, cretaceous, and tertiary, are alike abundantly represented in the rocks of that area, and that, in each case, their constituents closely resemble that of much lower latitudes. The first indications of the climate cooling in these regions is afforded by *Coniferæ*, which appear in the polar lower cretaceous formations. These are followed by the first appearance of dicotyledons with deciduous leaves, which again marks the period when the summer and winter season first became strongly contrasted. The introduction of these (deciduous-leaved trees) he regards as the greatest revolution in vegetation that the world has seen; and he conceives that once evolved they increased, both in multiplicity and diversity of form, with great rapidity, and not in one spot only, and continued to do so down to the present time.

Lastly, the advent of the miocene period, in the polar area, was accompanied with the production of a profusion of genera, the majority of which have existing representatives which must now be sought in a latitude 40° further south, and to which they were driven by the advent and advance of the glacial cold; and here Count Saporta's conclusions accord with those of Prof. A. Gray, who first showed, now twenty years ago, that the representatives of the elements of the United States flora previously inhabited high northern latitudes, from which they were driven south during the glacial period.

Perhaps the most novel idea in Count Saporta's essay is that of the diffused sunlight which (with a densely clouded atmosphere), the author assumes to have been operative in reducing the contrast between the polar summers and winters. If it be accepted it at once disposes of the difficulty of admitting that evergreen trees survived a long polar winter of total darkness, and summer of constant stimulation by bright sunlight; and if, further, it is admitted that it is to internal heat we may ascribe the tropical aspect of the former vegetation of the polar region, then there is no necessity for assuming that the solar system at those periods was in a warmer area of stellar space, or that the position of the poles was altered, to account for the high temperature of pre-glacial times in high northern latitudes; or, lastly, that the main features of the great continents and oceans were very different in early geological times from what they now are. Count Saporta's views in certain points coincide with those of Prof. Le Conte of California, who holds that the uniformity of climates during earlier conditions of the globe is not explicable by changes in the position of the poles, but is attributable to a higher temperature of the whole globe, whether due to external or internal causes, to the great amount of carbonic acid and water in the atmosphere, which would shut in and accumulate the sun's heat, according to the principles discovered by Tyndall and applied by Sterry Hunt in explanations of geological times, and possibly to a warmer position in stellar space, a more uniform distribution of surface temperature, and a different distribution of land and water.[1]

Before Count Saporta's essay had reached this country[2] another continuation of the subject of the origin of existing floras had been communicated to our own Geographical Society, by Mr. Thiselton Dyer in a lecture on "Plant Distribution as a Field for Geographical Research." Mr. Thiselton Dyer's order of procedure is the reverse of Count Saporta's, and his method entirely different. He first gives a very clear outline of the distribution of the principal existing floras of the continents and

[1] Professor Jos. Le Conte, in NATURE, vol. xviii. p. 668.

[2] Count Saporta's essay was presented to the International Congress of Geographical Science which met in Paris in 1875, and was not received in England till the autumn of 1878, though it bears date of 1877 on the title page.

islands of the globe, their composition, and their relations to one another, and to those of previous geological epochs. He then discusses the views of botanists respecting their origin and distinctive characters, and availing himself of such of their hypotheses as he thinks tenable, correlates these with those of palæontologists, and arrives at the conclusion "That the northern hemisphere has always played the most important part in the evolution and distribution of new vegetable types, or in other words, that a greater number of plants has migrated from north to south than in the reversed direction, and that all the great assemblages of plants which we call floras, seem to admit of being traced back at some time in their history to the northern hemisphere." This amount of accordance between the results of naturalists working wholly independently, from entirely different standpoints, and employing almost opposite methods, cannot but be considered as very satisfactory. I will conclude by observing that there is a certain analogy between two very salient points which are well brought out by these authors respectively. Count Saporta, looking to the past, makes it appear that the fact of the several floras which have flourished on the globe being successively both more localised and more specialised, is in harmony with the conditions to which it is assumed our globe has been successively subjected. Mr. Dyer, looking to the present, makes it appear that the several floras now existing on the globe, are in point of affinity and specialisation, in harmony with the conditions to which they must have been subjected during recent geological time on continents and islands with the configuration of those of our globe.

(*To be continued.*)

HAECKEL ON THE LIBERTY OF SCIENCE AND OF TEACHING[1]

PROF. HAECKEL has recently published his reply to the address on "The Liberty of Science in the Modern State," delivered at last year's meeting of the German Association, by Prof. Virchow. If we enter into this subject at greater length than is our custom with pamphlets we do so mainly from a sense of common fairness to both parties, since we reproduced Prof. Virchow's address *in extenso* (NATURE, vol. xvii. pp. 72, 92, and 111). We shall, however, confine ourselves merely to stating Prof. Haeckel's views on the subject, and leave it to our readers to judge of the value of his remarks for themselves.

In the preface to the little book before us Prof. Haeckel states that the general views developed by Virchow are in such complete contrast to his own that no reconciliation of the two is possible. Yet he refrained for a considerable time from publishing his reply; and this for two reasons. On the one hand, he thought he might safely leave the judgment of the strife between them to the future; first, because the evolution theory, which Virchow attacks, has, *de facto*, become the basis of biological science of the present day; secondly, because Virchow's objections to the theory of descent have been so frequently and thoroughly refuted that it seemed superfluous to refute them again. On the other hand, he felt great reluctance in opposing a man whom a quarter of a century ago he honoured as the reformer of medical science, and whose pupil and zealous admirer he was for many years.

"The more I for years regretted Virchow's position as the enemy of our new evolution theory, and the more I was challenged to reply by his repeated attacks upon it, the less inclination I felt, nevertheless, to appear publicly as the antagonist of the highly-honoured and meritorious man. If now I find myself forced to reply, I do so with the conviction that longer silence would only augment the erroneous views which my resignation hitherto has already produced. . . . . I must point out distinctly that it is not Virchow but I who am the person attacked, and that in my case there is no question of *attacking* a formerly highly-honoured friend, but of *defending* myself by necessity against his repeated and violent attacks. Another reason which compels me to speak at last lies in the continued fertile use made of Virchow's speech by all clerical and reactionary organs for the last nine months. . . . Already Friedrich von Hellwald has pointed out the great danger which lies in the fact that it was a Virchow who, under the banner of political Liberalism, and wrapped in the mantle of pure science, combated the liberty of science and of its teaching."

The author then continues to point out that the danger was never so great in Germany as at the present moment, where the political and religious life of the German nation seems to approach a profound reaction. The two mad attempts upon the life of the honoured and aged Emperor have called forth a storm of just indignation of such violence that even many Liberal politicians not only press for severe measures against the utopian teachings of social democracy, but, far overshooting the mark, demand that free thought and free teaching should be confined within the narrowest bounds. What more welcome support can the reactionary party wish for than that a Virchow should publicly demand the suppression of the liberty of science? The danger appears still greater to Prof. Haeckel if Virchow's great influence as a "liberal Progressist" is taken into consideration, now that the Prussian Diet will shortly open its debates on the educational law. "What," Prof. Haeckel asks, "may we expect of this educational law, if in the discussions Virchow, as one of the few authorities who will be consulted, raises his voice in favour of the principles which in his Munich speech he proclaimed as the safest guarantees for the liberty of science in the modern state. Article 20 of the Prussian Constitution, and § 152 of that of the German Empire say: Science and its teachings are free. Virchow's first action, according to his present principles, must be a proposal to cancel this paragraph. In view of the menacing danger, I cannot hesitate any longer with my reply. Amicus Socrates, amicus Plato, magis amica veritas!" The rest of the preface is concerned with a refutation of the "denunciation" by which Virchow wants to make the theory of descent responsible for the horrors of the Paris Commune. Haeckel thinks that by an intentional coupling of Darwinism with Social democracy, Virchow intended to do considerable damage to the former, indeed he sees in it an attempt to remove all "Darwinists" from their Academical chairs. At the same time he points out that nine out of every ten zoologists and botanists now teaching at European universities are Darwinists. Virchow's attempt is therefore perfectly futile, and will certainly never have any effect at Jena. "What the Wartburg was for Martin Luther, what Weimar was for the greatest heroes of German literature, what Jena has been during three centuries for a large number of scientific men, that will Jena continue to be for the evolution-theory of the present day, as well as for all other scientific theories which develop freely, viz., a firm stronghold for free thought, free research, and free teaching."

We now come to the first chapter, which is headed "Evolution and Creation." The author remarks at the beginning that nothing has so greatly facilitated the progress of the evolution theory, as the fact that its principal problem, the question of the origin of species, was placed before the alternative: *Either* organisms have been *developed* naturally, in which case they must descend from the simplest and common ancestral forms—*or* this is not the case, and the different species of organisms have originated independently of one another, in which case they can only have been *created* in a supernatural way, *i.e.*, by a miracle. Natural development or supernatural creation of species—the choice must here be made, since a third way does not exist. Since Virchow and many other antagonists of the evolution theory constantly mix this up with the theory of descent, and this again with the theory of natural selection or Darwinism, Prof. Haeckel does not think it superfluous to give a concise definition of each of the three great theories at starting. He then states his definitions as follows:—"The relation of these theories according to the present state of science is therefore simply the following:—I. *Monism*, the universal theory of evolution, or the monistic pro-genesis theory, is the *only* scientific theory, which *rationally* explains the universe and satisfies the desire for causality in the human mind, since it brings all natural phenomena into a *mechanical* causal connection as parts of a great and uniform (*einheitlich*) process of development; II. *Transformism*, or the theory of descent, is an essential and indispensable part of the monistic evolution theory, because it is the *only* scientific theory which explains the origin of organic species in a rational manner, viz., by transformation, and reduces this transformation to *mechanical* causes; III. The theory of selection, or *Darwinism, is up to the present the most important one* amongst the different theories, which try to explain the transformation of species by *mechanical* causes; but it is by no means the *only one*. Even if we suppose that most species have originated through natural selection, yet we know, on the other hand, that many forms called species are merely hybrids from two different species and are propagated as such; at the same time we

[1] Freie Wissenschaft und freie Lehre. Eine Entgegnung auf Rudolf Virchow's Münchener Rede über "die Freiheit der Wissenschaft im modernen Staat." Von Ernst Haeckel.

can easily conceive that other causes may be acting in the formation of species, causes of which we have no idea at present. To decide what importance natural selection has in the origin of species is left to the judgment of the various naturalists, and in this question the authorities differ materially even to-day. Some ascribe a greater, others a smaller importance to it. But the different estimation of the value of Darwinism is quite independent of the absolute validity of the theory of descent, because the latter is up to the present the *only* theory which explains, in a *rational* way, the origin of species. If we abandon this theory then nothing remains but the *irrational* supposition of a miracle, of a supernatural '*creation*.' We will briefly designate this mystical belief in a creation as 'creatism.' In this decisive and inexorable alternative Virchow has now publicly stated his belief in creatism and his disbelief in transformism." The author then dwells at some length on this, and quotes from the *Zeitschrift für Ethnologie*, edited by Virchow and Prof. Bastian, in which the lattter applauds Virchow's Munich address, and ridicules Haeckel's "deliramenta and absurdities." There is no doubt, therefore, that Virchow has confessed himself a "dualist and creatist," and is as convinced of the truth of his principles as Haeckel is of the contrary as a "monist and transformist," yet the former still refrains from acknowledging his principles in all their consequences. "On the contrary he still clothes his opposition in the favourite phrase of the clerical papers, viz., that the theory of descent is an 'unproved hypothesis.' It is perfectly clear, however, that this theory will never be 'proved' if the proofs in existence to-day are not considered sufficient. How often has it been repeated that the scientific certainty of the theory of descent is not based upon this or that single experience, but upon the *totality* of biological phenomena, upon the *Causal-nexus* of evolution? What are we to think, therefore, of the new proofs for the theory of descent which Virchow demands?"

In Chapter II. Haeckel undertakes to give some "certain proofs of the theory of descent." He shows that all general phenomena of morphology and physiology, of chorology and oecology, of ontogeny and palæontology, can only be explained by the theory of descent, and reduced to *mechanical causes*. The guarantee of the truth of the theory lies particularly in the fact that the last simple causes are the same for all these complicated phenomena, and that other mechanical causes cannot be imagined. "Where are we, therefore, to find still further proofs for the truth of the theory of descent? Neither Virchow nor any other of the clerical antagonists or dualistic philosophers show us where we possibly might have to look for further proofs. Where in the world are we to find '*facts*' which speak louder than the *facts* of comparative morphology and physiology, the *facts* of rudimentary organs and of embryonal development, than the *facts* of palæontology and of the geographical distribution of organisms—in short, than all the known *facts* from the most various biological domains?" If proofs by actual experiments are demanded, these proofs have also been furnished by the domestication of animals and plants, and their variations under such domestication. All working naturalists are perfectly well aware to-day that the *morphological* value of the word "species" is not an absolute but a relative one; nor has it any physiological value. Haeckel points out here that the class of animals which furnish the best "certain proof" that the conception of species has only a relative value, are the sponges: "their liquid form wavers to and fro with extraordinary uncertainty and variability, and makes all distinction of species quite illusory." The species question, one of the principal points in the theory of descent, is not even mentioned by Virchow, and Haeckel considers this highly characteristic. He arrives at the conclusion that Virchow has never thoroughly digested the evolution theory, and has never attentively studied Darwin's principal work on the Origin of Species, nor any other work by this author. The remainder of this chapter is devoted to an account of Virchow's activity, first at Würzburg, and afterwards at Berlin. Virchow left Würzburg for Berlin in 1856; it was at the former university that he made the celebrated application of the cell-theory to pathology, which caused quite a revolution in the latter science. Haeckel considers that the exchange of the narrow sphere for the wider one was not beneficial in its consequences, and that the Virchow of the present day has completely changed from the Virchow of 1848-1856; he points out that only those who are aware of the enormous progress morphology has made during the last twenty years, and have followed this science in all its details, can estimate the full value of the theory of descent, and of Darwin's theory of selection. "Whoever wishes to convince himself of what an enormous revolution was caused by these theories, in comparative anatomy particularly, let him compare the classical 'Grundzüge der vergleichenden Anatomie' of Carl Gegenbaur (1870) and his 'Grundriss' (1878) with the older books on this science. Of all the colossal progress of morphology Virchow has no idea, since he was ever a stranger to this domain. His great reforms in pathology lie in the domain of physiology, and particularly in that of cellular physiology. But during the last twenty years these two principal branches of biological research have separated more and more. The great Johannes Müller was the last biologist who could comprise the entire domain of organic natural research, and who acquired immortal merit in both branches alike. After Müller's death (1858) the two halves fell apart. Physiology, as the special science of the functions of organisms, turned more and more towards the *exact* and experimental method. Morphology, on the other hand, as the science of the shapes and forms of animals and plants, could of course make but little use of this method; it was bound to have recourse to the evolution theory, and thus became essentially a *historical* natural science. It was just upon this historical and genetic method of morphology, in contrast with the exact and experimental method of physiology, that I laid a particular stress in my Munich address. If Virchow, in his counter address, had really refuted the latter in its various details, instead of fighting it with phrases and denunciations, this contrast of principles would at least have been worth minute examination. Yet I do not wish to reproach Virchow with this, since he is completely involved in the one-sided views of the school-physiology of the present day, and because morphology lies far too widely apart from his domain, to make it possible for him to judge its methods and ends for himself. If, nevertheless, upon every occasion he pronounces a depreciatory judgment upon it, then we must question his *competence* in doing this. It is true that in his Munich speech he prints with large type the phrase, 'That which adorns me is the *knowledge of my ignorance*.' But I regret that I must deny him this adornment most completely. Virchow does *not* know how ignorant he is of morphology. Otherwise he would not have pronounced those crushing sentences regarding it; he would not constantly designate the theory of descent as 'a hobby,' or 'dreaming,' or as personal speculation, which now inflates itself on many domains of natural science.' Indeed Virchow honours me too much if he calls that my 'personal hobby' which for more than a decade has become the most valuable common property of morphological science. If Virchow were not so unacquainted with morphological literature he would know that it is already completely impregnated with the principle of descent; that in all morphological work which is carried on systematically and with a certain end in view, the theory of descent is now accepted as quite *indispensable*. But he is unaware of all this, and thus we understand why he continues to ask for 'certain proofs' for that theory when these proofs have in reality been furnished long ago."

Chapter III. treats of craniology as applied to the theory of the descent of man from the ape. Haeckel points out the importance of comparative and genetic craniology, but cannot help regretting that a great deal of time and labour has been wasted during the last ten years by "craniologists" with discussions as to the best method of measuring skulls, and also that numerous naturalists, Virchow among others, seem to have seen in "craniometry" the highest aim and object of craniological science, and to have forgotten what they really want to prove with their measurements. Turning to the question of the descent of man, the author remarks that the well-known phrase "man has descended from the ape," which is so often misunderstood and misapplied, can in the sense of the evolution theory but have this meaning: The human race as a whole has descended from the order of apes, *i.e.*, from one (or perhaps more) species of apes now long extinct; the latest ones in the long series of man's vertebrate ancestors were apes or ape-like animals. Of course none of the species of apes now existing can be regarded as the unchanged descendant of the old parental form. Virchow in his address expresses his doubt of the truth of the descent in question, while Haeckel looks upon it as one of the most certain phylogenetic hypotheses. He does not deny that the relative certainty of this as well as that of any other phylogenetic *hypothesis* cannot be compared to the *absolute* certainty of the *theory* of descent, and draws special attention to the great difference between the whole theory and any particular hypothesis relating to an individual order or class

of animals; such hypotheses are always dependent on our actual biological knowledge and may be changed at any time for better ones, while the theory as a whole needs no further proof; it is absolutely certain. But for the objective zoologist it is impossible, according to the principles of comparative systematics, to assign to man any other place in the animal kingdom than in the order of apes, or primates, as Linnæus calls them; this classification, which is inevitable, leads to the *common* descent of man and ape from *one* ancestral form; and this is the essential part of the question. The views as to the exact appearance of this ancestral form may be divided, but we must eventually arrive at the conclusion, if we consider all facts connected with the subject, that our long extinct ancestors can but have been real apes, *i.e.*, some placental mammal, which, if it existed to-day, we should certainly classify among apes. Finally, Haeckel points out how characteristic it is of Virchow's view on the matter that he again places palæontology into the foreground, and, before accepting the theory of descent, demands that an uninterrupted series of fossil transition forms between ape and man should first be found. As Darwin himself has minutely stated the reasons why the solution of this problem cannot be expected, and has shown the cause of the extraordinary incompleteness of the palæontological records, and of the natural impediments to a geological proof of the ancestral tree (in Chapter X. of the "Origin of Species"), Haeckel again arrives at the conclusion that Virchow has never attentively read Darwin's great work, and has never digested the teachings of palæontology.

Chapter IV. is entitled "Cell-Soul and Cellular Psychology." Haeckel states here that the views he expressed at Munich with regard to the soul of the cell, *i.e.*, "that we must indeed ascribe an independent soul-life to each organic cell," are but the natural consequence of Virchow's own teachings, viz., of the very fertile application which Virchow made of the cell theory to pathology. He then proceeds to give the definition of the word "soul" according to both philosophical theories, first according to the monistic or realistic theory, and then according to the dualistic or spiritualistic theory; he compares the simplicity of the former with the mystery and irrationality of the other. He adduces the various phrases in Virchow's address which leave no doubt on the subject that Virchow has completely abandoned the realistic theory in favour of the dualistic one, and shows the utter futility of Virchow's view that we cannot find psychic phenomena in the lower animals. "Volition and sensation, the most general and most indubitable qualities of all mental life, cannot be overlooked in the lower animals. Indeed, with most *Infusoria*, particularly with *Ciliata*, independent motion and conscious sensation (of pressure, heat, light, &c.) are so very evident, that one of their most patient observers, Ehrenberg, maintained up to his death that all *Infusoria* must have nerves and muscles, organs of sense and of mind (*Seelenorgane*) just like all higher animals.

"Now it is known that the enormous progress which science has recently made in the natural history of these low organisms has reached its climax in the maxim that they are *unicellular* (a maxim which Siebold pronounced thirty years ago, but which has been proved with certainty only recently); therefore in the *Infusoria a single cell* performs all the different functions of life, including the mental functions, which in the *Hydræ* and *Spongiæ* are divided amongst the cells of the two germinal lobes, and in all higher animals amongst those of the various tissues, organs, and apparatus of a complicated organism. . . . By the same right by which we ascribe an independent 'soul' to these unicellular *Infusoria*, we must ascribe one to all other cells, because their most important active substance, the protoplasm, shows everywhere the same psychic properties of sensitiveness (sensation) and movability (volition). The difference in the higher organisms is only that there the numerous single cells give up their individual independence, and like good state-citizens, subordinate themselves to the 'state-soul' which represents the unity of will and sensation in the 'cell-association.' We must distinguish between the central soul of the total polycellular organism or the 'personal soul' and the separate elementary souls of the single cells, or 'cell-souls.' This maxim is excellently illustrated by the interesting group of *Siphonophora*. There is no doubt that the whole *Siphonophora*-state has a very determined and uniform (*einheitlich*) will and sensation; yet each one of the single individuals which compose this state (or *Cormus*) has its separate personal will and sensation. Indeed each one of these is originally a separate *Medusa* and the 'individual' *Siphonophora*-state has resulted only by association and division of labour of this united society of *Medusæ*. Next to the unicellular *Infusoria* no phenomenon affords such ample and immediate proof for the truth of our cellular-psychology than the fact that the *human ovum*, like the ovum of all other animals, is a simple and single cell. According to our monistic conception of the cell-soul, we must suppose that the fertilised ovum already possesses *virtually* those psychic properties which in the particular mixture of parental peculiarities (*i.e.*, those of mother and father) characterise the individual soul of the new being. In the course of the development of the ovum the cell-soul of course developes itself simultaneously with its material substratum, and becomes apparent *actually* when the child is born. According to Virchow's dualistic conception of the 'Psyche,' we must suppose, on the contrary, that this immaterial being enters the soulless germ at some period of embryonal development (perhaps when the spinal tube separates from the germinal lobe?). Of course this way the pure *miracle* is complete, and the natural and uninterrupted *continuity of development* is superfluous."

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

St. Peter's College, Cambridge, has made a statute assigning one of its Fellowships to the Jacksonian Professor. It is intended to limit this professorship by statute to some branch or branches of chemistry or physics, a specially constituted electoral body, including representatives of non-resident science, making the selection freely on each occasion of a vacancy.

The site most favoured for the Sedgwick Memorial Museum, Cambridge, is Downing Street, in front of the present new museums. There will be a good opportunity of concealing from public view these extremely plain buildings and of erecting a satisfactory façade. The Sedgwick Committee have informed the University that 1,200*l.* is in their hands for this purpose, but this amount is insufficient, and the University, when better supplied with funds, must supply a good deal more. A Syndicate, including Drs. Paget and Humphry, Profs. Liveing, Newton, Hughes, and Colvin, has just been appointed to select a site, to obtain plans, to confer with the Sedgwick Committee, and report by midsummer next.

Prof. Leith Adams, F.R.S., has been appointed to the Chair of Natural History in the Queen's University of Ireland, rendered vacant by the lamented death of Prof. Harkness.

SOCIETIES AND ACADEMIES

London

Royal Society, November 21.—"On a Method of Using the Balance with great Delicacy, and its Employment to Determine the Mean Density of the Earth," by J. H. Poynting, B.A., Fellow of Trinity College, Cambridge, and Demonstrator in the Physical Laboratory, Owens College. Communicated by Prof. Balfour Stewart, LL.D., F.R.S.

The two chief causes of error in the use of the balance are:—1. Disturbances through changes of temperature, such as convection currents, or unequal expansion of the two arms. 2. The possibility that after raising the beam on the supporting frame and lowering it again, the same parts of the knife edges may not come into contact with the planes. Errors from the first cause may be to a great extent avoided by protecting the balance with a gilded case, and reading the oscillations from a distance by means of a mirror on the beam. The residual effects may then be detected by taking three observations at equal intervals of time, the first and third having the same weights in the pan, and their mean being compared with the second (*i.e.*, for a short time the disturbance is assumed to be a linear function of the time). The second cause of error has been removed by not raising the beam between successive weighings. For this purpose a clamp is placed underneath one pan, which can be brought into action at any time to fix the pan in whatever position it may be. The weights can then be interchanged while the counterpoise (Borda's method being employed) maintains the beam in the same state of flexure, and the knife edges always remain in contact with the same parts of the planes.

The value of a given deflection was estimated by riders, and the weights were interchanged each by special arrangements.

The greatest deviation from the mean in the comparison of two 1 lb. weights in one group of twenty comparisons, when the weather was unfavourable, was 1·20 millionth of 1 lb., while in another group of twenty-seven comparisons (the weather being much finer and more favourable) the greatest error was 1·50 millionth.

To determine the mean density of the earth, a 1 lb. weight was hung from one arm of the balance at a distance of about six feet below it, and was accurately counterpoised in the other pan. A large sphere of lead (about 340 lbs.) was then alternately inserted under the hanging weight, and withdrawn. The difference which its attraction made in the weight of the hanging weight was about 1·45 millionth of 1 lb. This increase of the weight was measured as accurately as possible by means of riders on the beam of the balance. Comparing this with the attraction of the earth on the weight—that is, its weight—we can calculate the mass of the earth in terms of the mass of the lead sphere. The results hitherto obtained are only preliminary, though they seem near enough to former determinations to show that with improved arrangements which the author intends to make, a good value may ultimately be obtained. The mean of 11 determinations is 5·69, with a probable error of 0·15.

Physical Society, November 23.—Prof. W. G. Adams, president, in the chair.—Prof. Ayrton read a paper on the music of colour and of visible motion, which we give elsewhere. —Dr. Schuster then described his new method of adjusting the collimator of the spectroscope for parallel rays of different refrangibility. His plan is very simple, and is based on the fact that if the rays entering the prism are parallel, the focus seen in the telescope will remain constant when the prism is turned round, but if they are not parallel, the focus will shift. The process, therefore, consists in looking through the telescope while turning the prism. If the focus shifts, the collimator has to be adjusted until no shifting takes place. The adjustment must be made with a prism whose sides are perfectly plane, and a good one may be kept for the purpose.

Statistical Society, November 19.—A numerous list of candidates were balloted for and elected Fellows.—The Howard prize medal, with 20*l*., has been awarded to Surgeon John Martin, L.R.C.S. Edin., of the Army Medical Department, at present serving in India with the Royal Artillery. An *extra* prize medal has also been awarded to Capt. H. Hildyard, of the 71st Highland Light Infantry, his essay being scarcely inferior to that of Mr. Martin.—The President, Mr. G. J. Shaw-Lefevre, M.P., in his opening address, commented on the past work of the Society, especially the papers read by its members during the past session, and the various statistics collected through its operations. Their great object was to study the past so as to understand the present and be able to give a forecast of the future.—Prof. Jevons afterwards exhibited and explained to the meeting the arithmometer of M. Thomas, long in use among actuaries.

EDINBURGH

Royal Society, November 25.—The following office-bearers were elected:—President, Prof. Kelland; Vice-Presidents, David Stevenson, C.E., Bishop Cotterill, Sir Alexander Grant, Bart., David Milne Home, Sir C. Wyville Thomson, Prof. Douglas Maclagan; General Secretary, Prof. Balfour; Secretaries to Ordinary Meetings, Prof. Tait, Prof. Turner; Treasurer, David Smith; Curator of Library and Museum, Alexander Buchanan; Council, Prof. Fleeming Jenkin, Rev. R. Boog Watson, Dr. Hugh Cleghorn, Prof. T. P. Fraser, Prof. Rutherford, Dr. R. M. Ferguson, Rev. W. Lindsay Alexander, Dr. Thomas A. G. Balfour, J. T. Buchanan, Rev. Thomas Brown, Robert Gray, and Dr. William Robertson.

PARIS

Academy of Sciences, November 25.—M. Fizeau in the chair.—The following papers were read:—Critical examination of a posthumous writing of Claude Bernard on alcoholic fermentation, by M. Pasteur. He represents this writing as a sterile attempt to substitute for facts well established the deductions of an ephemeral system.—On the reduction in continuous fractions of $e^{F(x)}$, $F(x)$ designating an entire polynome, by M. Laguerre.—On isosceles figures, by M. Badoureau.—Reply to various communications by M. Levy.—Reclamation of priority, in regard to M. Werdermann's communication on an electric lamp, by M. Regnier.—On a new phenomenon of static electricity, by M. Duter. In certain cases electrification may change the volume of bodies. A large thermometric envelope containing water is made into a condenser by pushing a piece of platinum wire into its exterior, and fixing outside a sheet of tin. Whenever, like a Leyden jar, it receives a charge, the water is observed to descend, remain stationary while the charge persists, and resume its former level on discharge. It is inferred that the glass is dilated. With any kind of armatures the same result is had. Another experiment was to place the above-mentioned arrangement in another thermometric envelope containing water; on electrifying, the water in the measuring-tube of the outer envelope rose, while the other fell. M. Jamin recalled the fact that M. Govi, ten years ago, made an experiment similar to M. Duter's first, and attributed the effect to a contraction of the liquid; M. Duter's second experiment proves that the expansion of the glass is really the cause.—Reply to a note of M. Meunier on the artificial crystallisation of orthose, by MM. Fouqué and Levy. M. Meunier (they hold) had not sufficient data to determine the nature of the minerals produced; his experiments are a mere repetition of those of James Hall in 1798, who fused natural rocks, subjected them to long annealing, and found the metal grains obtained had sometimes a crystalline texture. The authors, far from having got results with orthose like those of M. Meunier, find a marked difference between this felspar and others as to its structure after reproduction by igneous fusion; it does not take the ordinary crystalline structure, and this reveals the necessity of intervention of volatile elements in genesis of acid rocks.—Note on the element called *Mosandrum*, by Prof. Lawrence Smith. He claims priority in having called attention to the absence of the oxide of cerium, and to new characters of certain earths in the mineral samarskite, and having indicated a new one he called *mosandrum*.—Double stars; certain groups of perspective, by M. Flammarion. He gives a list of couples that are merely optical groups, due to the meeting, in the same visual ray, of stars situated one beyond the other in space, and having different proper motions.—On the number of complete arrangements where consecutive elements satisfy given conditions, by M. André.—On various derivatives of spirit of turpentine, by M. De Montgolfier. He has studied the action of sodium chiefly in chlorhydrates of turpentine, solid and liquid.—On a cyanised derivative of camphor, by M. Haller.—Action of salts of chromium on salts of aniline in presence of chlorates, by M. Grawitz. He notes the advantage of using these salts in place of vanadic salts; they are less rare and dear, and have even greater energy. $\frac{1}{10}$ of a milligramme of bichromate of potash, per 125 grammes of aniline salt dissolved in water, still developes black.—On the physiological action of borax, by M. De Cyon. Borax added to meat to the extent of twelve grammes daily (a quantity ten times that required by the Jourdes process), may be taken in food without causing the least disorder in general nutrition. Substituted for marine salt, borax increases the power of assimilating meat, and may cause a large increase of weight in the animal, even when the alimentation is exclusively albuminoid. This all applies to pure borax only.

LORD RAYLEIGH'S "THEORY OF SOUND"

The Theory of Sound. By J. W. Strutt, Baron Rayleigh, F.R.S. Vol. II. (London: Macmillan and Co., 1878.)[1]

THE second part of Lord Rayleigh's highly instructive work on acoustics contains the mechanics of oscillatory motions in liquids and gases. Atmospheric air is that medium by which by far the greater number of sound-waves are conveyed to our ear, since it is only exceptional that this happens through solid bodies which are in contact with our teeth or with the bones of the skull. But it is just for this reason that all circumstances are of considerable importance, which influence the transmission of sound-waves in the air, *i.e.*, change either their velocity, their direction, or their intensity. This part of the theory has been worked out very minutely and completely by the author. We find here the compilation and demonstration of a large number of facts which, in other works on acoustics, are hardly mentioned. The author, after having first developed (in Chap. XI.) the general laws of the motion of liquids as expressed in hydrodynamical equations, and then explained the difference between rotational and irrotational motion of fluids, passes on to the simplification of the equations, which is determined by the circumstance that with sound, as a rule, we have to do with oscillations of extremely small amplitude. First, the motion of plane waves is investigated, and it is shown that with waves which move only in one direction half their equivalent of work consists in the *vis viva* of motion, and the other half in the potential energy of the compression and dilatation of the medium. Then follows the explanation of the influence which the change of temperature, taking place with compression or dilatation of gases, exercises upon the velocity of transmission of sound. It is shown, in the manner first employed by Prof. Stokes, that if a perceptible quantity of heat could be exchanged between the compressed and dilated layers of the waves during the lapse of one oscillation, the intensity of the sound-waves would very quickly decrease in their transmision and they would die away.

The subjects treated of up to this point are generally known among physicists; less known are a series of other results of the theory. The author next gives a comparatively very elegant and easily intelligible demonstration of the results at which Poisson and Riemann arrived, when investigating the propagation of sound-waves for which the velocities of oscillation are no longer infinitesimal when compared to the velocity of transmission. It appears that the different layers of the wave transmit their phases with different velocities, viz., with that velocity which represents the sum of the ordinary velocity of transmission of the smallest waves and of the oscillation velocity of the particles of air oscillating in the same direction. The compressed layers of the wave, therefore, are propagated quicker than the dilated ones, thus they must gradually change the shape of the wave, and finally overtake the preceding dilated layers. What would happen in that case, whether perhaps a breaking of the waves of air would take place, is not yet clear, since the hydro-dynamical equations apply only to velocities changing continuously.

These circumstances have not always been considered in experimental researches concerning the velocity of sound. A precise answer to the question regarding the magnitude of this velocity can only be given, if we confine ourselves to oscillations of extreme smallness.

The author has also investigated under what conditions a sound-wave of finite amplitude can move forward without changing its form. It appears that this could happen only under the supposition of a special law for the compressibility of the medium, which does not correspond with the law applying to gases.

The propagation of sound in the atmosphere is subjected to yet other perturbations, which partly arise from the different temperatures and moistures of the superposed strata, and partly from the different force of winds. At the surface of water or extensive masses of solid substance, the sound-waves of the air are totally reflected even under very small angles of incidence; under perpendicular incidence their reflection, although not total in the strict sense of the word, is nearly as complete. For that part of the sound which enters the new medium, the same law of refraction holds good which applies to waves of light. But also from a surface of hydrogen one-third of the sound coming through air at a vertical incidence is reflected, and the angle of incidence for total reflection is not larger than $15\frac{1}{4}$ degrees.

The problem to determine theoretically how the propagation of sound in the atmosphere is changed by the different temperatures of its strata cannot yet be solved completely. However, it can be ascertained in what direction the most powerful effect must travel. On account of the great dimensions of the strata of the atmosphere, compared to which the wave-length of the large majority of audible tones disappears entirely, the conditions of the propagation of sound are similar to those of light. We may imagine the sound-waves dissolved, as it were, into rays of sound, and then look upon each separate ray as being almost completely independent of the motion of its neighbouring rays. This is no longer admissible if obstacles are in the way of the travelling sound, the dimensions of which exceed the sound wave-lengths only in moderate proportions, as is the case in our houses and rooms, with the transmission of sound through windows and doors. Then, as in the case of light under similar circumstances, diffraction takes place. The great difference in the propagation of sound and light, as it becomes evident in ordinary experience, has its cause in the very different magnitude of wave-lengths. The greater the wave-length the greater the diffraction on the passage through the same aperture. These circumstances, which are forgotten so frequently, the author considers in Chapter XIV. When sound is propagated in the unbounded space of the atmosphere the conditions of the problem are such, that they allow of its decomposition into rays of sound. If a source of sound is near the ground then its sound rays are all bent into an upward direction, as Prof. Osborne Reynolds first pointed out, and those which travel in a direction parallel to the ground are mostly annihilated through friction or other obstacles. The sound proceeding from

[1] For Vol. I. see NATURE, vol. xvii. p. 237.

a source near the ground is, therefore, not heard far off by an observer standing on the ground. It is heard at a much greater distance if the observer or the source of sound be in an elevated position. The state of the atmosphere will have great influence upon these conditions. In dry air and sunshine the deflection of sound upwards will be greater than in moist air which forms clouds above, or during rain.

The decrease of temperature in the upper strata of the atmosphere causes sound to travel at a lesser speed than in the lower ones. Now if a wind is blowing, the velocity of which increases with the height, then, as Prof. Stokes remarks, this causes an increase in the velocity of the sound-waves in the direction of the wind, and a decrease in velocity in the opposite direction; thus, for sound which travels in the former direction, the retarding effect of decrease of temperature is neutralised, and for that travelling in the latter it is augmented. We therefore hear better if the wind blows towards us from the source of sound than if the contrary takes place. Indeed, by an upper windy layer, sound produced in the lower tranquil air may be totally reflected. This influence of wind is remarkable also because it forms an exception to the law demonstrated by myself, viz., the law of reciprocity in the propagation of sound, if the sound-source and the observer change places.

The problems of the reflection of sound by fixed walls, for instance, the phenomena of whispering-galleries, speaking-trumpets, and the echo, are treated in the same manner. Although here the admissibility of the decomposition of sound into sound-rays does not, as a rule, appear quite so unquestionably justified, yet the phenomena observed agree with this hypothesis on the whole.

An essential progress in the application of the theory upon experiments has been made by the author in the calculation of the influence of the open apertures of organ pipes and resonators upon their pitch. In my own demonstration of this part of the theory I had started from those forms of motion which did not render the calculation too difficult, and had then derived the corresponding forms of pipes; finally, I had so determined the optional constants of my hypotheses, that the form of pipe approached the form wished for, the cylindrical one, for instance; yet I remained confined to a few forms if I did not wish to complicate the calculation too much. Lord Rayleigh, on the contrary, supposes a given form of pipe, and has employed the maxims, developed in the first volume of his work, regarding the variation of conditions under which sound-motion takes place, to determine the limits within which the true value of the desired magnitude must lie, and has indeed been able to draw these limits so narrowly for the most important problems, like that of the cylindrical open pipes, that practically the solution is perfectly sufficient. In this way he has been able to treat simultaneously a number of problems, which hitherto had not even received an approximate solution, for instance, the determination of the proper tones of resonators of the shape of bottles with wide body and narrow neck.

Besides the problems mentioned, which are of direct importance to experimental physics, a series of others are worked out, where the mathematical solution can be completely given, such as the propagation of sound in balls, spherical layers and rectangular boxes filled with gas, the reflection of sound from the outer surface of a ball, and the communication of sound to air by oscillating balls and strings. These problems are valuable not only as theoretical exercises, but also with regard to our understanding of physical phenomena. They are examples affording to the mental eye of the physicist a particularly perfect insight into the essence of sound-motion and the changes it undergoes, when the conditions under which it occurs are changed. Thus he obtains quite as good a conception of the typical behaviour of sound as if he had actually seen the phenomena, and this conception will also guide him safely in cases of observation, where the exterior conditions are not as simple as they are in the theoretical example.

At the end of the volume Lord Rayleigh has placed the words: "The End." We hope that this may be only the provisional, not the definite end. There is still an important chapter wanting, viz., that on the theory of reed-pipes, including the human voice. For the former, at least, the principles of their mechanics can already be given, and the methods the author employs seem to me to be particularly well adapted for further progress in these domains.

After reed-pipes we would mention the theory of singing flames, and the blowing of organ-pipes. In the latter case the leaf-shaped current of air, which comes from the wind-case, forms a sort of reed, which oscillates under the influence of the oscillating column of air in the interior of the pipe, and which throws its air now into the interior of the pipe, and now outside.

Altogether, the whole of this important class of motions, where oscillatory movements are kept up through a cause which acts constantly, deserves detailed theoretical consideration. The action of the violin bow, and the sounding of the Æolian harp, also belong to this class.

Lord Rayleigh certainly deserves the thanks of all physicists and students of physics; he has rendered them a great service by what he has done hitherto. But I believe I am speaking in the name of all of them, if I express the hope, that the difficulties of that which yet remains will incite him to crown his work by completing it.

H. HELMHOLTZ

OUR BOOK SHELF

Zoologischer Anzeiger. Herausgegeben von Prof. J. Victor Carus. (Leipzig: Wilh. Engelmann.)

THE idea of a zoological "advertiser" seems to us a most excellent one, and we both welcome and heartily recommend to our readers who are interested in the animal kingdom this little fortnightly journal of Prof. Carus. The editor purposes to publish a number every two weeks, each number to contain from sixteen to eighteen pages, and the yearly subscription to be six shillings. The first number bears the date of July 1, 1878, and already a dozen numbers have appeared. The plan of each number is to commence with a retrospect of the current literature of zoology, a retrospect that we need hardly say will be well done by one so learned and able in the matter of bibliography as the editor of that most necessary work, the "Bibliotheca Zoologica." Then each number contains some short notices on zoological subjects in connection with museums, chiefly such as have a practical bearing. Thus in No. 2 we find an article by G. von Koch, of Darmstadt, on a method by which sections can be made of substances of different

degrees of consistency without altering the relative position of the same, which cannot fail to be of interest and value to such as wish to make and mount thin sections of corals or alcyonarians, while in most of the numbers there are under this head to be found notices of collections for sale or specimens to be exchanged, and when this journal becomes, as we have no doubt it will, known to all directors and assistant-directors of zoological museums we anticipate for this section a very extended use. Another portion of the journal is devoted to short notices on general zoological subjects. Thus No. 11 contains a short notice by Prof. Salensky, of Kasan, on the embryology of the ganoids; one by Prof. Goette, of Strasburg, on the development of the bones in the limbs of vertebrates; a note by Dr. A. Gruber, of Freiburg, on the formation of the oviducts in the Copepods; one by Prof. Entz, of Klausenberg (Hungary), on the evolution of gas from the protoplasm of some protozoa, in confirmation of a record of the same fact by Prof. T. W. Engelmann; and one by Prof. E. Martens, on our knowledge of thread-spinning snails.

Another characteristic of this new journal is that, under the heading "Personal-Notizen," will be found a very exact list of all the museums and schools of anatomy and zoology in the world, commencing with those in Germany. This list has now got as far as Belgium. The directors' and assistant-directors' names, with those of the professors and assistant-professors, are given in full, and if, when the list is complete, an index of the names of the various teachers in all the colleges and schools were added, the list would serve many a useful purpose.

We feel persuaded that this most useful little journal will require only to be known in this country to be duly appreciated, and we wish its talented editor every success in his undertaking. E. P. W.

La Vegetacion del Nordeste de la Provincia de Entre-Rios. Informe Cientifico. Del Dr. Don P. G. Lorentz. (Buenos Aires, 1878.)

THIS is a book, or rather a pamphlet, of 179 pages of closely-printed matter, and illustrated by two maps of the country described, the nature of which with regard to its vegetation is very carefully recorded in the first division, which occupies forty-seven pages. The second part consists of a list of species arranged scientifically under each natural order, the paragraph referring to the individual plant comprising such information as to the frequency or scarcity of the species, the colour of the flowers, period of flowering, and any properties for which the plant may be economically valuable. These lists are useful in many ways, for instance they often show the widespread geographical range of many well-known plants, and in the lists before us we find many European introductions. A separate list of thirty-two species of fungi is added, and some notes on the maps given.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Was Homer Colour-Blind?

UPON reading Dr. Pole's two papers (NATURE, vol. xviii. pp. 676, 700) my first feeling was to ask: "But how could

'The blind old man of Scio's rocky isle'

know anything at all about colour?" Presuming, however, that the tradition of his blindness might be unwarranted, and further, that it may be a mistake to suppose, as many do, that the "Iliad" is a collection of rhapsodies by different poets, I again asked myself: "Are there in Homer more anomalies in the nomenclature of colours than may be accounted for by the vague use of words? Are there more than we should find in this country among uneducated men of the labouring class?" About two years ago I made extensive inquiry as to the prevalence of colour-blindness among children, and in the village schools of this part of Somersetshire I found that the girls could name the neutral as well as the other tints readily and correctly, but that many of the boys had but about half-a-dozen words to use, and would refer orange to red or to yellow, and purple to brown or to blue, merely for want of terms; for they could match the test papers with other papers, or with the girls' dresses.

If we refer to the old ballads and early romance poetry of our own and other languages, we shall see that the popular poets of the middle ages, like the peasant boys of the present day, misused terms of colour as much as Homer; although the many beautiful paintings that still exist prove that people could see and distinguish colours as well then as now, and that Mr. Gladstone's theory of a development of the sight from one generation to another is a mere delusion. Certain terms are adopted and handed down traditionally as stock epithets in poetry and technical terms in trades. They are known to be wrong, but they are used from habit.

Dr. Pole assumes that the colour-blind see black and white as others do; or, to use his own words (p. 700), that their vision in regard to them is normal. This I doubt. One of the gentlemen who is so affected tells me that he cannot distinguish snow upon the steps of his front door. Now if white is a combination of all the colours of the prism, and we omit red and green, there will be seen a combination of blue and yellow, and these when spun together in a colour top produce stone colour, which I believe to be the white of those who have a dichromal vision. As to black, it is singular that in Anglo-Saxon *blac* means not "black," but as the Flemish *bleek* and Germ. *bleich*, "pale," a case in point to show the instability of language in these matters.

To take Homer's terms *seriatim*:—

Ἐρυθρός.

A poet must not be pronounced colour-blind if he compares wine to blood, and calls it red.

"The king sate in Dumfermline town, drinkin' the *bluid-red wine*."
Sir Patrick Spens, l. 1.

"And aye she dighted her father's wounds, His *blood* ran down *like wine*:"
Douglas Tragedy, st. 8.

Conversely, in slang language to give a man a bloody nose is to "tap his claret." The chair-cushion upon which I am sitting and the curtain of my window are of a dark crimson, but in the language of upholstery would be called "maroon." Now *marron*, from which the word is derived, is a Spanish chestnut, and that is a full brown without any visible red in it.

In our old English ballads and early romances, and in the German, Flemish, Swedish, and Danish, and in some more modern poems gold is constantly called "red" and "ruddy;" as in Dryden:—

"A crown of ruddy gold enclosed her brow."

In a German ballad by Ehrhardt, "Die Nonne," st. 5:—

"Was zog er von seinem Finger? Einen Ring von *Gold so roth*."

In a Flemish ballad of the sixteenth century called "Het Soudaen's Dochterken" in Thijm's "Gedichten," v. i. p. 246:—

"Sijn hayr dat blinckt van verwe schoon,
Als waer het *roode gouden*."

In an ancient Swedish ballad called "Gångarpilten," Arwidss v. ii. p. 156:—

"För jag har intet *rödt guld* att sätta mod er.

And in the corresponding Danish ballad, Dan. Viser iv. p. 122:

"Jeg haver ei *det röde guld*."

Milton, "Paradise Lost," bk. ii. l. 889, calls flame "ruddy flame."

In old herbals, as in that of Lyte, fol. 1578, p. 162, marigolds are called "Ruddes." "They be called in Englishe Marygoldes and *Ruddes*."

Hair, such as is usually called "red hair," is better named in Greek πυῤῥός, fiery; for certainly its colour is widely different from blood. Where in the Old Testament the word "red" is applied to horses and heifers, the Greek of the Septuagint has πυῤῥοί.

What is really red is on the contrary called by Jenner "pink" in the well-known poem upon the signs of wet weather:—

"Closed is the *pink-eyed* pimpernel."

To come to the very age we live in, old croquet-players persist in calling the second ball of the series "pink," although for the last ten years it has always been painted red.

Now if English should become a dead language, what will some future critic suppose *red* to have meant? a term that he finds applied to blood, to gold, to wine, to the marigold, to flame, and to bay horses; and replaced with *pink* in the case of the pimpernel and the second croquet-ball?

Φοίνιξ.

This word meant originally Phœnician, a people from whom the richly-dyed robes that they imported were called; as in an old poem we have a colour designated from Bristol:—

"Her kirtle *Bristol red;*"

and as a deep blue dye is called "indigo" from being first brought from India.

The same word φοίνιξ was applied to horses, probably Syrian ones in the first place, just as from Rouen we call those of a certain colour "roan," agreeably to a common usage in all languages. Thus porcelain is called "China," and a certain leather made of goats' skin "Morocco," although manufactured in Europe.

As to the term φοίνιξ being applied to the lion and the jackal, we may well suppose that Homer never saw the one or the other. It is quite as unlikely that he ever saw a live dragon. If the horses that the Phœnicians introduced were tawny, it would be no misnomer to call the lion and jackal φοίνιξ. We are not to presume that if Phœnician robes were crimson, everything else that was named after them must also have been crimson. A future critic might as reasonably argue that porcelain from China was of an orange colour, because there are "China oranges."

Dates were also called φοίνιξ as being a Phœnician fruit, just as the small grapes imported from Corinth are called "currants."

Ῥοδόεις.

This term referred, no doubt, to a crimson variety of rose, the so-called Damask rose, the one usually cultivated in ancient times. Thence a comparison of its colour to blood implied by a line of Bion:—

Αἷμα ῥόδον τίκτει τὰ δὲ δάκρυα τὰν ἀνεμώναν.

Where this word is applied to oil in the account of the funeral of Patroclus (Il. xxiii. 186), it is to a heavenly oil with which Venus anoints the corpse of Hector to preserve it from putrefaction, and not ordinary olive oil:—

ῥοδόεντι δὲ χρῖεν ἐλαίῳ Ἀμβροσίῳ.

It may have meant either "rose-coloured" or "rose-scented."

Κυάνεος.

This term, which seems in so many passages to mean "dark," would have been very properly applied to the sand of volcanic islands, like those in the Egean Sea. On the coast of the Gulf of Naples near Pompeii it is quite black, and walking over it on a hot sunshiny day I had cause to remember its colour, for my feet were roasted.

Χλωρός.

Grass in the Mediterranean countries soon withers and dries to a pale colour, and remains so the greater part of the summer. It was to this withered grass that Homer seems to have compared a pale complexion, and honey, and olive wood, and the nightingale. Our evergreen meadows are unknown in the south.

Οἶνοψ.

The houses of the ancients were unprovided with glass windows, and were very dark within, so that entertainments must have been given by lamp-light, when wine of a dark colour would have appeared darker still.

Πορφύρεος.

A vague term, but equally vague our *purple;* for while we apply it to the foxglove and many other flowers which present an equal mixture of red and blue, we at the same time apply it to a beech, the foliage of which is of a deep copper colour merging into black without any blue in it at all; and in milliners' language to a deep blue without any red in it.

Ἰοειδής.

What was the flower that the Greeks called ἴον, is very doubtful. That which Pindar describes (Ol. vi. 91) as with ξανθαῖς καὶ παμπόρφυροις ἀκτῖσι, with brilliant yellow and richly purple rays, cannot be our own modest violet. I have always supposed it to mean Centauries of different species, some of them, as the *C. ragusina*, of the brightest gold colour, others, as the *C. cyanus*, of a clear blue, and others of a dark purple. The late J. Hogg in his treatise upon the classical plants of Sicily most unaccountably omits all mention of it. At the present day it is the stock, *Matthiola incana*, which in Italy is called *Violetta*. In the above line quoted from Pindar it must have been a radiate flower that he intended. In this respect uncultivated nations are very inaccurate. The Illyrians at the present day call all wild flowers alike indiscriminately *rosje*, roses; and we may be sure that Jesus Christ in his beautiful apologue—"Consider the lilies"—used the language of the people he was addressing, and did not mean lilies in the strict sense of the word; plants that would not burn if cast into an oven on the morrow of being cut down.

It is very strange that Mr. Gladstone in the essay published in the *Nineteenth Century* of October, 1877, has entirely passed over κροκόπεπλος, saffron-robed, an epithet twice applied to Eos, the dawn of day, in the first lines of "Il.," bk. 8 and bk. 19, a word that proves that Homer saw yellow distinctly; for he never calls Eos yellow-fingered, κροκόδακτυλος, or rosy-robed, ῥοδόπεπλος.

In the above it has been my desire to prove that any inaccuracy in Homer's names of colours was due to the unfixed character of the language, and not to a defective vision on the part of the poet. In illustration of this view let me give a case that occurred to me about two years ago. I took to a flower show at Taunton a dahlia of a rather common variety, and such as most gardeners would call purple; a dark pink with a shade of blue over it, and requested forty-four different people to write me down what they would call its colour. In their replies I got fourteen different names for it. I sent a flower of the same kind to a lady who returned me twelve replies from members of her family and friends, and in the twelve were eight different names. How much more then may we expect diversity and inaccuracy in the nomenclature of their colours among the popular poets of an early period! and how little reason have we for believing in any gradual development of colour vision in successive generations of men!

R. C. A. PRIOR

Colour-Blindness

IN answer to Mr. Podmore's question in NATURE, vol. xix. p. 73, as to the appearance to me of the green of the solar spectrum, I may say that such part of it as inclines to yellow is seen by me as faint yellow, and such part of it as inclines to blue is seen by me as faint blue. The line of division, which I may call neutral green, appears simply colourless or white; there is no dark space, no pigments; neutral green appears to me gray.

When I wrote the paper for the *Phil. Trans.* I applied the descriptions to colours obtained by pigments, because that was the mode that had previously been adopted in treating the subject, and I had not, at that time, the opportunity of making any good observations on direct light. At a later period I went through a series of experiments of the kind with an eminent physicist, but I am not aware that the results have been published. I will endeavour, if possible, to supply the desideratum.

WILLIAM POLE

The Colour Sense

THE note of Mr. Grant Allen in NATURE, vol. xix. p. 32, induces me to state that in the year 1877 I arrived at and developed exactly the same conclusions in several articles of the German journal, *Kosmos* (vol. i. pp. 264-275 and 428-433), namely:—

1. The colour-sense manifestly appears already in insects and many of the lowest vertebrates; its complete absence could therefore hardly be supposed in the very lowest race of men.

2. The anomalies shown in the expressions of colours among the most ancient civilised nations by Gladstone, Geiger, and Magnus, may be perfectly explained, partly by the insufficiency of the primitive store of words for this subject, partly by climatic, physiological, and optical reasons, as stated at length in the above-mentioned articles.

3. The usage of telling terms for the single colours closely followed the progress of the art of dyeing. ERNST KRAUSE

Berlin, December 2

History of the Speaking Telephone

As the writer of the article on the history of the telephone, to which so eminent an authority as Prof. Watson takes exception in the long and interesting letter he has contributed to your columns, perhaps you will allow me to say a few words. Prof. Watson expresses his "astonishment at the claim now made that he (Mr. Gray) anticipated Mr. Bell in the invention of the speaking telephone," and speaks of the "erroneous statement of facts" contained in the article in question (NATURE, vol. xviii. p. 696). Unfortunately Prof. Watson has not specified the statements which are erroneous, and appears to have overlooked the fact that the article is a review of the works of Mr. Prescott and M. du Moncel on the telephone, and that the "statements of facts" are chiefly quotations from those works. At the same time, using all the materials within my reach, careful inquiry had led me to concur, and in that article I expressed my concurrence in the following opinion, quoted from Count du Moncel's book:—"Si M. Bell a été le premier à construire et à rendre pratique le téléphone parlant, M. Elisha Gray avait le premier conçu le principe de cet instrument."

Gray and Bell were both exhibitors at the Philadelphia Exhibition, and Prof. Watson, writing as one of the judges of the scientific instruments exhibited, shows that whilst Gray merely submitted to the judges an apparatus for the multiple transmission of musical notes, and no speaking telephone, Bell not only exhibited a speaking telephone, but towards the end of June (1876) the judges, Prof. Watson and Sir William Thomson, obtained with Bell's instrument the clearest evidence of the electric transmission of speech;[1] whereupon Mr. Gray was both surprised and incredulous, and even after the publication of Prof. Bell's discovery, he delivered a lecture exhibiting his musical telephone, but making no mention of a speaking telephone.

If the Philadelphia Exhibition were the only means for scientific publication during the year it existed, Prof. Watson's letter would effectually dispose of Gray's claim. An exhibition, however, is not the place for conceptions, but for accomplished facts, and I believe no one denies that to Mr. Bell is due all the credit of having been the first to construct, and that entirely independently of Gray, an articulating electric telephone. Gray's claim, as I take it, rests on his having registered in the American Patent Office, on February 14, 1876, "a means of transmitting and receiving vocal sounds telegraphically," and the drawing he gives of his invention shows a correct appreciation of the true principle of an articulating telephone, to which his previous researches had been gradually leading him.

I should be sorry to appear in any way to depreciate the splendid achievement of Prof. Bell through having referred to other workers in the field of electric-telephony. In fact up to the time the article in NATURE appeared, I fear that, through ignorance, I had done but scant justice to Mr. Gray, having attributed the conception of the principle of an articulating telephone solely to Prof. Graham Bell.

There are two points in the history of the telephone upon which I should be very glad to have authoritative information from Prof. Watson or other of your American readers; the first relates to the claim made by Prof. Dolbear, and the second to the introduction of the ferrotype diaphragm. W. F. BARRETT

Royal College of Science, Dublin, December 9

[1] I am glad to learn the exact date of the trial in question, which was given as August in the article.

The Formation of Mountains

IN the account of M. Favre's experiments in NATURE, vol. xix. p. 103, I find the following passage:—"It is, in fact, very probable that our globe is at the stage when, according to Élie de Beaumont, 'the mean annual cooling of the mass exceeds that of the surface, and exceeds it more and more.' It must follow that the external strata of the globe, tending always to rest on the internal parts, are wrinkled, folded, dislocated, depressed at certain points, and elevated at others."

The whole theory of these dislocations, &c., thus depends on the assumption that the interior of the globe is cooling more rapidly than the crust. This has always seemed to me an impossibility, and even an absurdity, and I shall be very glad if any of your correspondents will explain how it is possible. I have always understood that the surface of the earth does not now derive any appreciable portion of its heat from the interior; but if the interior is cooling rapidly, to what can it part with its heat but to the crust? Volcanoes and hot springs no doubt allow a certain portion of heat to escape, but it must be an infinitesimal part of the heat of the entire mass. If the meaning of the statement is, that the heat received from the sun now keeps the surface at a permanent mean temperature, quite irrespective of central heat or cold, and that therefore the loss of heat by volcanoes, &c., causes the centre to cool while the crust does not—this may be admitted, but it is doubtful whether it can have any bearing on the effects observed. For, on this theory, all the compression would take place in that shallow superficial layer which is kept above its normal temperature by the sun's radiation; and as we go back into past time this superficial layer would be thinner and thinner. But all geological evidence goes to show that folded and contorted rocks were subject to compression at considerable depths; and further, that such contortion was greater in comparatively early than in very late geological times—both facts directly opposed to the theory in question. Will any one of our great physicists enlighten us? ALFRED R. WALLACE

AFTER reading your *résumé* of Prof. Alphonse Favre's interesting experiments on the formation of mountains by lateral thrust, it occurred to me that it would be easy to devise a mode of experimenting which would more nearly correspond with what takes place in nature. In M. Favre's experiments the lateral thrust was simply in one direction. In nature it is in all directions.

If a disk of india-rubber were stretched by means of a steel ribbon bent into a circular spring, on letting the spring slowly recoil there would be a lateral contraction of the india-rubber in all directions. A layer of clay upon that disk would, I think, show not the transverse inequalities of M. Favre's drawings, but a diversified unevenness more nearly resembling the actual surface of the earth. ARTHUR RANSOM

Leicester, December

New Galvanometer for Strong Currents

I OBSERVE in NATURE (vol. xviii. p. 707) an article on a new galvanometer for strong currents by Mr. Eugen Obach. I published a paper on the same form of galvanometer seven years ago, and inclose a copy of my paper which was published in the *American Journal of Arts and Sciences*, vol. ii., August, 1871. JOHN TROWBRIDGE

Harvard College, Cambridge, Mass., U.S.A., November 23

Explanatory

I MUST ask you, in common fairness, to allow me to protest against P. G. T.'s mistaken statement (vol. xix. p. 71) respecting a sentence which he quotes without the explanatory context. The moving force exerted by the earth on the moon as a whole is of course precisely equal to the moving force exerted by the moon on the earth. I had not to learn this from P. G. T., but had said so in so many words. But the moving force exerted by the earth on a given amount of matter in the moon is eighty-one times greater than the moving force exerted by the moon on an equal amount of matter in the earth. P. G. T. will scarcely deny this, and he cannot deny that the whole statement from which he quotes one sentence meant this, and this only. Nor, if he did, would any one who has read the chapter on the moon's motions in my treatise on the moon, believe such a statement.

He quotes a passage from my last book without comment, but, unfortunately, not without serious alteration. Apart from the undue emphasis which he thus gives to certain parts of it, the passage expresses my honest opinion. That I may be mistaken is quite possible. Men are always misunderstanding each other. If I find I have erred, I will acknowledge as much.

Until the word "heat" ceases to be used in common speech in two senses, or I am shown that when used for "temperature" (as when we say blood heat, boiling heat, a heat of 90° F., and so forth), it can be understood to mean "caloric," I intend always so to use it in familiar writing about science. I deliberately struck out the word "temperature" wherever I had used it, and replaced it by the word "heat," in the same way and for the same reason that I often replace the word "velocity" by the

word "speed." If in any passage ambiguity has thus been occasioned—or, as I would rather say, if anything I have thus said can be mistaken—I shall be glad to hear of it and set it right.

I must have failed, however, to make my meaning clear to P. G. T. in pp. 194 and 240. If at least he rightly understands me, I must leave him to settle with observed facts in one case and with the recognised authorities in the other.

My account of the earlier experiments of Professors Andrews and Tait was taken, as stated, from a paper by Prof. Heaton. P. G. T. ought to know the facts, and I accept his correction. When my article was written, several years ago, the "now received idea" was not yet received. I did not err in calling that theory "beautiful" and "ingeniously conceived" which is now generally accepted. But if I had, it is a less serious mistake to describe a sound theory as still open to doubt, than to describe a doubtful theory as demonstrated. This the author of the sea-bird theory of comets might remember with advantage.

RICHARD A. PROCTOR

Graphic Granite

I HAVE been spending some time of late in the examination of the rocks of this district, and was pleasantly surprised, a few weeks back, at finding some well-marked specimens of graphic granite among the waste material raised from Huel Agar Mine. It very closely resembles that found at Portsoy, N.B., but the felspar is grey instead of red. As I am not aware that this interesting rock is known to exist in any other locality in England, the observation may be worthy of record.

W. End, Redruth, December 2 FRANK JOHNSON

The Phonograph and Vowel Sounds

IN the interesting paper on "The Phonograph and Vowel Sounds" (vol. xviii. p. 340, *et seq.*), the authors remark that although the general results are the same as I have inferred from my own researches, the special numbers expressing the distribution of total intensity of vowel sounds among the partial tones are very different. Perhaps you will have the kindness to communicate to your readers the following reasons explaining, as I believe, the differences mentioned above.

1. The tables given by the authors, which contain the distribution not of intensity but of amplitudes, must be altered in a manner readily seen in order to be comparable with my tables.

2. The marks impressed by the phonograph contain certain peculiarities which, although without influence on the tones spoken from the instrument, remain effective in modifying the form of the curves obtained by mechanically transferring them.

3. The objective intensity (kinetic energy) determined by the authors is nearly, but not quite, proportional to the subjective intensity (quantity of sensation) which I have measured with the aid of resonators.

4. As I have observed, the differences of English and German pronunciation cause remarkable differences in the distribution of total intensity of vowel sounds among the partial tones.

Taking the above points into consideration it will be seen that the differences mentioned by Messrs. Jenkin and Ewing appear much smaller.

Besides I am pleased to notice that the authors, like myself, consider the flexibility of mouth cavity as important in explaining, where it exists, the characteristic pitch and other properties of vowel sounds.

F. AUERBACH

Local Colour-Variation in Lizards

THIS subject has recently been very fully discussed by my friend, Dr. Max Braun, assistant in the zoological laboratory of the University of Würzburg. His paper, which has especial reference to the lizards of Minorca and of some of the smaller islets of the Balearic group which lie round that island, is entitled "*Lacerta Lilfordi* und *Lacerta muralis*," and will be found in Part I. of the fourth volume of Prof. Semper's "Arbeiten aus dem zoologisch-zootomischen Institut in Würzburg," published in May, 1877.

Braun refers constantly in this paper to a memoir by J. von Beidraga, entitled "Die Faraglione-Eidechse und die Entstehung der Farben bei Eidechsen," which was published at Heidelberg in 1876.

P. HERBERT CARPENTER

Eton College, December 9

The Range of the Mammoth

ON November 6 Prof. Boyd Dawkins read a paper before the Geological Society on "The Range of the Mammoth in Space and Time." As the professor and several other recent writers have taken it to be proved that *Elephas primigenius* occurs in pre-glacial beds, it will, perhaps, be as well at once to review the evidence.

Geologists often speak of "pre-glacial beds" when they only mean beds beneath some one boulder clay, perhaps No. 6, or even later in the list given below. The succession is roughly as follows :—

6. Hessel Boulder Clay	Upper, Middle, and Lower of the North of England (?)
Hessel Gravel	
5. Purple Boulder Clay	Upper, Middle, and Lower of Lincolnshire, &c. (?)
Bridlington Crag	
4. Chalky Boulder Clay	Upper, Middle, and Lower of East Anglia.
Mid-glacial[1]	
3. Contorted Drift[1]	Lower Boulder Clay of the Norfolk Coast.
Sands[1]	
2. Second Till[1]	
Intermediate Beds[1]	
1. First Till[1]	
Arctic Freshwater Beds.[1]	
Temperate Freshwater Beds.[1]	Pliocene.
(Land surface.)	
Weybourn Beds, estuarine,	
including the "Forest Bed."[1]	

As the *lower* boulder clay of Northwich, in Cheshire, appears to be No. 5 or No. 6, and consequently newer than the *upper* boulder clay of East Anglia, the molar of *E. primigenius* found beneath it need not be pre-glacial. The Hertfordshire boulder clay, beneath which Prof. Prestwich found a tooth is, I believe, No. 4.

In East Anglia I have seen two molars of *E. primigenius* from the contorted drift, No 3 in the list, but it has not yet been found lower. All the specimens said to come from the forest bed have been dredged or picked up on the beach, and are of no value as evidence. At Bacton, on the Norfolk coast, I dug out a jaw and three teeth of the mammoth from a post-glacial deposit; if the denudation of the cliffs had proceeded these teeth would have been found on the beach mixed with those of *E. meridionalis*. There appears to be one specimen, and one only, found *in situ* in the Forest Bed which can with any probability be referred to *E. primigenius ;* this was found some years ago by Mr. Savin, of Cromer, it has not yet been satisfactorily determined, but from its peculiarity and the difference of opinion about it, it appears certainly not to be the ordinary form.

CLEMENT REID

Egton Bridge, Yarm, Yorks

The Bunsen Flame a Sensitive Flame

IT is not generally known, *if* it has ever been noticed before, that the Bunsen lamp gives a flame sensitive to sounds. A lamp should be chosen which has a tendency to "burn below;" this may usually be secured by opening the air passages to the utmost and lessening the supply of gas. The flame should burn quietly. My most sensitive flame is four inches high; the gas at about one inch pressure of water. A smart tap with a penholder on a glass cylinder a yard from the flame causes the characteristic "ducking," which is sometimes so energetic as to extinguish the flame or to cause it to burn below. The acute sound of rattling bottles, of a glass rod against a beaker, and many such familiar sounds of the laboratory, are the most effective. This may explain burning below without obvious cause. A tap on a mortar with the pestle twenty feet distant from a well-adjusted flame causes it, and so, often unintentionally, we may have the same result.

Preston, December 3

OUR ASTRONOMICAL COLUMN

JEAN DOMINIQUE CASSINI.—In the course of his examination of the older archives of the Paris Observatory, which had been placed at his disposal with unrestricted permission to make extracts for use in his lunar re-

[1] These will be described in the Geological Survey Memoir on the Cromer Cliffs

searches, in the first instance by Delaunay and afterwards by Leverrier, Prof. Newcomb discovered that the wide-spread belief that Cassini I. was director of the Observatory, which is even stated to have been the fact in French histories of astronomy, is an error. The establishment appears to have been assigned for the common use of the Academy of Sciences, and no such office as that of director was known or recognised. Prof. Newcomb suggests it may have been the celebrity of Cassini which gave rise to the impression that he was director of the Observatory. Of the astronomical records of that time preserved in the archives a large portion were evidently never intended to be understood or used except by the observers themselves. The note-books have no titles, no indications of the observer or indications of the instruments employed, except in the case of clocks: each observer seems to have had his own instruments, without any reference to or comparison with those of others. In the earlier observations no designations even of occulted stars were attached, so that it was necessary for Prof. Newcomb's investigation to calculate the places of the moon as affected by parallax for the times of observation before the objects could be identified, an operation which, though laborious, was always successful except in the cases of a few small stars. Lalande, in his notice of the work of Cassini I., does not call him director of the Observatory at Paris. Louis XIV., he states, applied to the Pope, Clement IX., for permission for Cassini to pass some years in Paris, where the Academy of Sciences was in course of formation, offering him, through Colbert, 9,000 livres per annum for the period of his residence in France. He arrived at Paris on April 4, 1669, and his reception by the French king was such that he wished to remain permanently in the country. The Pope offered opposition at first, which the king succeeded in overcoming, and Cassini was naturalised, and, as Lalande says, obtained a considerable fortune. He commenced observations at the Paris Observatory in September, 1671.

THE SECOND COMET OF 1582.—In the list of cometary radiant-points and meteor-showers in the Report for 1877 of the Luminous Meteors' Committee of the British Association, the distance of this comet's orbit at the descending node from the earth's path is stated to be 0·00, and the conjunction with the cometary shower is fixed to November 9 for 1875. This is a mistake, whichever orbit of those calculated may be adopted for the comet. Pingré, in his *Cometographie*, gave two sets of elements, the second being calculated apparently with the view to bring in Santucci's reported observation of a comet on March 10, of which he was the only observer. Tycho observed the comet on May 12, 13, and 17, and it is upon the observations on these three days that the orbits depend. They were reduced with modern elements by Mr. Hind (*Astron. Nach.* No. 880), and from the resulting positions, D'Arrest calculated elements in 1853. In 1865 Mr. Marth, after rectifying one oversight in the reduction, also computed an orbit, and his elements will no doubt be preferable to the other systems, though they do not differ materially from D'Arrest's in *Astron. Nach.*, No. 891. Mr. Marth's elements are as follow:—

Perihelion passage 1582, May 6·4485 M.T. at Uraniburg.

Longitude of perihelion	255 16 43	Equinox
" ascending node ...	227 13 33	of 1582.
Inclination	61 25 51	
Log. perihelion distance	9·22716	

Motion—retrograde.

Whence the comet's radius-vector at descending-node is 2·87, or the comet is far outside the earth's orbit at that point in its path. The radius-vector at the opposite node is 0·18, so that there is no near approach to our track.

The comet of 1582 was observed by the Chinese for about twenty days from the day of discovery, May 20. Their annals have no reference to Santucci's comet, the existence of which is doubtful, but we follow Pingré in designating Tycho's comet—the second of the year.

GEOGRAPHICAL NOTES

AT the meeting of the Geographical Society on Monday evening, after a few remarks from the Earl of Dufferin, who occupied the presidential chair for the first time, Mr. C. R. Markham, C.B., read three papers on Arctic matters. In the first he treated of the Swedish expedition, of the progress and results of which we have kept our readers informed. The second paper was devoted to the Dutch expedition in the *Willem Barents* during the past season, the results of which are by no means insignificant. Experience of the ice movements between Spitzbergen and Novaya Zemlya was acquired, and a full hourly series of meteorological observations taken, as well as deep-sea soundings with serial temperatures and magnetic observations. Natural history collections were also made, and Mr. W. G. A. Grant, who was in the *Pandora* in 1876, succeeded, in spite of almost constant fogs, in completing an excellent series of photographs. Lastly, Mr. Markham dealt with the best route for future Polar discovery, which he considers to be along the west coast of Franz Josef Land.

WE have to hand a report on the results of the preliminary polar expedition conducted by Capt. Tyson in the *Florence*. The vessel wintered from October 10, 1877, in lat. 66° 13′, at the head of Cumberland Gulf, Amisto Harbour. The published maps locate this place 2° further north. Last winter was very severe, almost an unbroken succession of storms of rain and snow. The *Florence* was not frozen in until the latter part of November, and after the middle of May the ice was unsafe. The coldest temperature was −52° F. on January 21; the highest, on June 9, was 55°·5. The longest period of cold was from March 5 to 13, when the thermometer averaged about −40°. The variations of the thermometer were often from 6° to 8° in a single hour, when the wind was veering. The site had never been visited by any naturalist, but the fauna was found by Mr. Kumlein almost identical with that of Baffin's Bay, with only a few notable and apparently unaccountable exceptions. Some North Pacific species and one European were found by Mr. Kumlein, Birds do not occur in any notable number, except perhaps the eider-duck. Some rare eggs were procured, and a good series of skeletons of young and fœtal seals. The flora appears to be extremely meagre. The same species were collected on the Greenland coast, in lat. 70° N., much more luxuriant and abundant. A considerable collection of lichens was made, and a good series of algæ was collected. Only ten species of fishes were met with, some of them, it is true, of interesting forms. The family collected are of Silurian age. Esquimaux skulls and old implements were procured.

A GOOD deal has been said of late as to the practicability of opening trade-routes to the Chinese province of Yünnan from the side of Assam, Burmah, Tonquin, and even Russian Turkestan, and it is, therefore, not uninteresting to note from the Pakhoi Consular Report that the Chinese have a route thither through the south of the empire, of which we believe foreigners have not heard before. Communication between Pakhoi, on the southern sea-board of Kwang-tung, near the Tonquin frontier, and the province of Yünnan is carried on by the west River pass Nanning-fu to Peisi-ting, thence over the mountains, or still by the West River, in very small boats, to Kwangnan-fu, in Yünnan. In addition to the natural difficulties of the route, the border-land of the two provinces is a wild and lonely region, infested by bands of robbers. The valuable trade which will some day spring up with the rich south-eastern part of Yünnan, not devastated during

the Mohammedan rebellion, will, no doubt, take the route of Haiphong, as it is shorter than that of Pakhoi, and has practicable water-communication throughout its whole length.

THE latest news from Dr. Gerhard Rohlfs informs us that he is at Tripoli, under the protection of the French consul. He was to proceed to Wadai on December 15, and was daily expecting rich presents from the Emperor of Germany, which he was instructed to offer to the new sultan of this remote kingdom.

DR. CREVAUX, the explorer of French Guiana, has reached the source of the Oyapok, and crossed the range which separates Oyapok from the Amazon basin.

L'Exploration, of December 7, contains several interesting letters from M. Soleillet, who, it will be remembered, started some months ago from the French West African settlements for exploration of the African interior. His last letter is dated from Kouniakary, the capital of Segou, from which he hopes to reach Timbuctoo.

ACCOMPANYING an article on the Bolan Pass in the December number of the *Geographical Magazine* is a map of the Bolan, the Mula, and other Passes, by Mr. Trelawny Saunders, an admirable specimen of accurate and carefully executed cartography.

ARE THE FOSSIL FLORAS OF THE ARCTIC REGIONS EOCENE OR MIOCENE? AND ON THE CAUSES WHICH ENABLED THEM TO EXIST IN HIGH LATITUDES[1]

THE question of the conditions and their origin under which floras, presumably requiring a temperate climate, were enabled to exist in Polar regions has been so frequently discussed both before and since the recent Arctic Expedition, that it is strange to find any aspect of the subject having remained unnoticed.

There are some points, however, which can be by no means regarded as conclusively settled, and upon these I wish to say a few words. In the first place the age of the so-called miocene floras has, I believe, been wrongly interpreted. Again, the temperatures required by them may have been over-estimated. Lastly, there seems to me to be no occasion whatever to invoke astronomical causes or to invent recurring periods of heat and cold, of which we have no geological proof, in order to account for their former presence there.

In the first place, then, if we examine the palæontological evidence, the only kind on which the age of the rocks has been decided, we find that it is very far from conclusive, and instead of pointing to a common miocene age for all the tertiary beds in the Arctic regions, we find that there are many reasons for believing some of them at least to be eocene. The plant evidence is, indeed, in the present state of our knowledge, almost negative; but what similarity there is in the floras to those of the miocene is directly against their being of that age instead of in favour of it, *for no two floras which are much alike and met with in widely separated latitudes can possibly have been contemporaneous, although floras of quite distinct facies may have been so.* The fact that a proportion of the plants have been identified by Heer with those of the miocene of Switzerland is of no weight whatever, as a considerable proportion are equally identified with the undoubted eocene lower lignitic of America, and a number of forms in the latter again with the miocene of Switzerland. The truth is, that at present any formation containing dicotyledons may be, with almost equal plausibility, referred to either eocene or miocene to suit the author's requirements; for besides the similarity in the ovate and lanceolate leaves from both, many species actually range right through them. Were the age of the Alum Bay and Bournemouth beds not thoroughly established, from their fossil leaves, even they would certainly have been referred to miocene. This will not, I am happy to think, always be the case, for there are a great number of plant forms which appear to be decidedly typical of, and confined to, each stage respectively. Already a number of hitherto supposed miocene deposits in Europe have been recognised as eocene, and as soon as those forms which from their range are of negative value, have been set aside, the confusion will cease. I have, indeed, strong hopes that we may be able to recognise each stage in the eocene of temperate latitudes by its plants, more from the incoming of new and distinct types, however, than the continued presence of older forms.

The confused way in which floras of many ages have been mixed together, seems to me to have arisen in a very simple manner. The flora of Oeningen must undoubtedly be accepted as a typical miocene flora, and contains but very few eocene forms—if indeed any. It contains, however, many plants common to other isolated fragments of strata which contain mixed floras, that is, floras with percentages of eocene as well as miocene plants. There being no typical series from undoubted eocene available as standards of comparison, the plants common to the miocene have alone been taken to determine the age of these beds, and the unknown eocene forms have thus been enrolled as miocene, and in their turn used to identify other still more distinctly eocene beds as miocene; much in the same way that the Barton beds were formerly identified, from their possessing a few species in common, as London clay, and the species peculiar to the Barton horizon, subsequently made use of to identify *calcaire-grossier* and Bracklesham beds in their turn with the London clay.

The oldest Arctic flora containing dicotyledons, and which, therefore, has any bearing on the subject, is that of Kome in North Greenland. It is mainly composed of ferns and gymnosperms, and its age may probably have been correctly inferred. The next beds, referred to the upper cretaceous, appear to be approximately of the same age as the Dakota beds, and therefore, in my opinion, decidedly supra-cretaceous relative to that formation in Europe.

We have next, if Heer's nomenclature is right, an immense gap right from the cretaceous to the miocene, to which latter he has referred all the rest of the obviously newer beds. He does not account in any way for the absence of eocene deposits, and relies exclusively on plant evidence, which I think should be, for the present, absolutely set aside. Before quitting the subject of the plants, I wish it to be understood that I in no way intend to disparage Heer's judgment. Considering the nature and condition of the specimens submitted to him, it is a marvel that he could have drawn and described them in so admirable a manner. But Heer has unfortunately never had a large series of definitely eocene plants to describe, and hence almost all his floras are cretaceous or miocene. I profoundly respect his work, and only to strengthen my plea that leaf evidence may be temporarily set aside or reconsidered, I mention that already three floras pronounced by Heer to be miocene, have since proved one cretaceous and two eocene; and still others must follow.

Assuming that I may be allowed for the present to dismiss the plants, I will touch upon the purely physical evidence, which seems to me to be, small as it is, entirely in favour of the eocene age of the beds. In the first place we have the great probability that eocene remains would, if they had ever existed, be found in their proper sequence, considering the number of widely-separated places in the North Polar area from which plant-remains have been obtained. It is certain that they must have existed, since the area continued land throughout eocene times, for there are no marine deposits of that age; and there is

[1] This was written before attention was called to Saporta's address at the anniversary meeting of the Royal Society.

abundant evidence of more than one kind that Europe and America were connected then, and that animals and plants passed between them. Besides that, the floras themselves contain both American and European types, and during the middle eocene a great number of plants were common to both continents.

In the next place the temperature of the eocene period in Europe was much hotter than that of the miocene, and therefore presumably more favourable to the growth of such floras in northern latitudes. To call them miocene we have to admit the former existence of a climate sufficiently uniform to have enabled the same species of plants to grow simultaneously from Italy and the United States to the 70th parallel, a state of things not in accordance with our present experience of plant distribution. But if we assume them to be eocene, the decreasing temperature which prevailed from that time to the miocene would have gradually and naturally driven the forms southward, and thus the very similarity of the miocene floras of America and Switzerland to those of the Arctic regions, renders it most unlikely that they were of the same age, and almost certain that the latter were considerably older.

In comparing the eocene and miocene temperatures we find, as already stated, that the former most readily accounts for the growth of temperate floras in high latitudes. Taking Heer's estimate that the miocene temperature in the latitude of Switzerland at the sea-level was only 9° C. warmer than at the present day, the progressive decrease of heat to the north is not so much in accordance with that of the present time, as it is found to be on the supposition that they belong to the eocene; we have to suppose that the mean temperature diminished in a less degree.

Speaking roughly, the present decrease in the isotherm from latitude 50° of south England, to that of Spitzbergen, is about 10° Fahr. for every 10° of latitude. This is as nearly as possible the ratio of decrease between England and Greenland in eocene times as implied by the floras, supposing them to be of one age. If, as I assume from all the data I can collect, England in middle eocene times possessed a mean annual temperature of 70° F., Greenland would naturally have had one of 50°, which is that assigned to it by Heer (9° C.). The decrease thence to Spitzbergen and Grinnell-land is hardly less rapid, being about 1° F. (½° C.) of cold for each degree of latitude. Heer calculates—principally on the mean temperature required by Platanus—that between Greenland and Spitzbergen, 8° lat., it was 4° C., but very unaccountably fancies that between Spitzbergen and Grinnell-land no further decrease took place, and upon this assumes that trees might have extended to the very Pole itself. The evidence against it, however, seems perfectly clear, for all the planes and limes, and more temperate forms have disappeared, and the genera found there, with a single exception, have representatives which at the present day live within the Arctic Circle. This exception, Taxodium, judging from its present habitat, Mexico and the Southern United States, would necessitate a climate completely different from that required by all the other plants with which it is associated. They form a distinctly Arctic assemblage: the spruce, especially, is never met with fossil to the south, except in inter-glacial beds. The fossil Taxodium must, therefore, only be looked upon as an allied extinct species, whose resemblance to living forms does not imply identity of habit, since all other considerations are against it. A similar instance is found in the willow, which is generally characteristic of the north; yet *Salix humboltiana* is found in the Amazon districts and *S. safsaf* in Egypt; and similarly, although Cassia is eminently characteristic of tropical and subtropical zones, *C. marylandica* flourishes on the banks of the Lake of Geneva. As it is essential to get rid of the evidence of Taxodium, if we are to suppose this former climate followed the present natural laws, I shall refer to some remarks by Lesquereux upon the nearly allied redwoods.

In describing the pliocene plants of California, he concludes that they are related to the present flora of the Atlantic slope, and not to that of California. He accounts for their destruction on the eastern side by the powerful agencies of glacial action, marine submersion, and long-sustained volcanic cataclysms. When these had ceased the sheets of water between the Missouri River and the Rocky Mountains and the mountains themselves prevented the old flora from again occupying the Western area. Some of the pliocene species, however, were preserved through the glacial epoch in California, but modified, for the most part, by the cold conditions they had undergone. "The two species of *Sequoia*—one the more predominant, the other the more remarkable, of the flora of California—are evidently also remnants of the pliocene. *S. gigantea*, which in all probability covered the higher slopes of the mountains of that epoch, has been destroyed everywhere, except in some deep valleys. . . . The other, *S. sempervirens*, left here and there, has again taken the ascendency under more favourable physical circumstances. Its present distribution explains its preservation until the present epoch. According to Prof. Bolander, "the distribution of the redwood depends upon sandstone and oceanic fogs. Where either one of these conditions is wanting there is no redwood. The redwoods begin in the northern part of Monterey County, in isolated groups, in deep, moist cañons. A short distance south of Monterey City, on the Monterey Bay, a white bituminous slate sets in, and extends nearly to Pajaro River. On this no redwood is found, but *Pinus insignis*. At Pajaro River, eight to ten miles from the ocean, they set in again, and extend to nearly twenty-eight miles south of this city (San Francisco), either in deep cañons, or in groves extending over several ridges eastward, as far as the fog may reach. Then they continue in similar localities to latitude 42°, the state boundary."

The existing allied species withstood a glacial period in California; there is no improbability in supposing that older and extinct species may have habitually supported a cold temperature. It appears that they belong to a very old type, now confined to a limited area, and becoming extinct, at whose survival we cease to wonder when we reflect that individual trees have been calculated to be 3,000 years old. To pass through the life of such a species, an enormous period must be required, for only 100 generations might carry us back 300,000 years, with as little modification as an annual plant might undergo in 100 years. The sandstone soil and damp sea fogs required by them in their native habitat, may explain the difficulty in getting them to grow under cultivation except in comparatively warm latitudes—and it is upon plants under cultivation Heer's estimate in Europe is based—but lessens our surprise that they should have existed in Greenland or farther north during the eocene time.

Apart from Taxodium, therefore, there is every evidence, in the disappearance of temperate forms and the preponderance of conifers of boreal type, that, as at the present day, there was a natural and progressive decrease of temperature to the north between Grinnell-land, Spitzbergen, and Greenland.

In the next place I would call attention to the possibility that the respective temperatures thought to be requisite for the growth of such associations of plants as are found fossil in these various lands may be in excess of the minima which would have sufficed. If this were the case, it would of course remove to a slight extent an argument I have just brought forward against the miocene age of the deposits. One of the conditions peculiarly favourable to the growth of trees in northern latitudes is the protracted length of the summer days, and it is an

ascertained fact that they require less heat in latitudes above 60°, owing to this rapid lengthening of the days. The chemical action of the sun's rays seems in some way to compensate for feeble warmth, and vegetation receives more impulse from the presence of the sun than from temperature in the shade. As examples of this, De Candolle[1] mentions that *Fagus sylvatica* exists in the north with a less temperature than it can support elsewhere; and that the limits of growth of barley prove the point conclusively.

It appears certain, according to De Candolle, that in very few cases has even intense cold, during natural periods of rest, any injurious influence upon plants, and that their northern limits are not determined by excess of cold but by want of heat. The destructive agents are late spring frosts, or premature heat followed by chills; and so fatal are their effects that one week in May has killed entire stocks of sub-tropical plants which had stood considerable frost in winter. There is no doubt that many plants would grow in much colder latitudes if the temperatures of each month were cyclically regular. *Fraxinus excelsior*, L.,[2] supports great cold, especially when accompanied by fogs, and penetrates as far north as 64°. *Ilex aquifolium*, L., reaches latitude 62° in Norway, and, like Abies, is limited in range, not by excess of cold, but want of heat. *Evonymus europæus*, L., is found just within 60°, and must occasionally suffer intense cold. But perhaps the well-known *Chamærops humilis*, L., affords the most striking familiarly-known instance of capricious distribution. It is indigenous to Nice in latitude 40°, yet it is not found anywhere in Italy, with a trifling exception, until Calabria is reached. Under cultivation it bears a very considerable amount of winter frost, the limit of which I have not ascertained, nor the minimum it encounters at Nice. I merely mention these instances as indicating possible sources of error, for were Chamærops extinct and found fossil at Nice, we should infer from it, with every appearance of probability, that the temperature of Nice had been the same as that of Sicily or Granada, the more normal homes of the palm.

One of the most remarkable facts connected with Alpine or Arctic plants is the length of time they can endure the absence of light while they are covered with snow, and when thus protected they would be unaffected by even Arctic cold. Evergreens, as we see by the Alpine rhododendron, are equally unaffected, and I have in Switzerland seen laurels, bays, and acubas shrouded in snow for many weeks without injury. I will mention but one other instance of the extent to which trees will sometimes bear cold, quoted by Herschel.[3] "In the valley of the black Irkut, in Siberia, Atkinson found a ravine filled with ice, and with large poplars growing in it, with their trunks imbedded 25′ in snow and ice, while the branches were in full leaf. Around each stem was a hollow of 6″ thawed and full of water." Besides mere heat and cold there are many influences known and unknown which limit the range of plants. The distribution of the vine is a case in point, for it is well kown that in historic times it was extensively cultivated in England, Normandy, and parts of Prussia, in which it will no longer ripen its fruit.

While the winter temperatures in these Arctic regions, if accompanied by snow and fogs, may have been of extreme severity, the summer temperature need not have been high, for the present Arctic and Alpine plants, including roses, species of Betula, Salix, Empetrum, Vaccinium, and conifers need but little heat.

Having attempted to show that the amount of heat really required was not so large as has been imagined, I will endeavour to prove that it, even upon Heer's assumption, might easily have been furnished by physical causes which we know did, in all probability, exist in eocene time, and were quite independent of astronomical causes and change in the position of the earth's axis, of which there seems to me no proof whatever, geological or otherwise. At least, to qualify this assertion, if such have existed in the past, there is no need to invoke them in this particular case. Central heat may, of course, be dismissed as having had too little influence in eocene time to be appreciable.

We may roughly estimate, on Heer's basis, that the average temperature between the latitudes and longitudes of England and Iceland was not more than from 15° F. to 20° F. warmer in eocene (or miocene of Heer) times than it is at present, and we may assume also on the evidence we possess that the present climate would permit any of the eocene floras, supposing they still existed, to grow in latitudes not more removed from those in which they are found than 15° to 20° farther south. For example, the English eocene flora could now exist in Madeira, the Iceland eocene flora in the Isle of Wight, that of Spitzbergen in Sweden, and that of Grinnell-land in Northern Norway. We have therefore to seek for some cause adequate to produce a difference in the temperature of Greenland, for instance, equal in degree to that of 20° F. or 20° latitude as a maximum. Following upon a map the isotherms of the 70th parallel, we see that Prince Albert Land has a temperature of but 5° F., whilst Lapland, in the same latitude, has one of 32° F. There is evidently here a cause at work capable of influencing the temperature to the extent of 27° F.; therefore a more powerful cause than is required. The same map shows us obviously that this agent is the sea. Wherever the Arctic waters find egress or penetrate the land, the isothermal lines around the Pole are deflected south. In like manner the line denoting the limits of trees is in many places pushed back more than 10° S. by the ice-laden water flowing from the Arctic Ocean. From Lapland to Siberia it is, except for a short distance, within the Arctic circle, principally within the 70th parallel. Nearing Behring's Straits it is sharply deflected south by the Polar Sea, but away from its influence, it as suddenly rises and again (North America) far overlaps the Arctic circle, until it once more comes under the influence of the cold seas and channels penetrating south into Hudson's Bay, which drive it to below the 60th parallel. Avoiding Greenland, it includes part of Iceland and the whole of the North Cape, owing to the influence of the Gulf Stream. The influence of this warmer water, cold as it is here, is no less remarkable, for, by merely shutting off the Arctic currents from close proximity to the shore, it enables trees to grow on the coast, and at a point on the Arctic circle between Iceland and the Norwegian coast, raises the temperature, according to Herschel, full 20° above that which is normal to the latitude.[1]

We thus see that the limit of trees enters the Arctic circle wherever the land has a great extension south or where the Gulf Stream raises the temperature, but that it especially shuns wherever the Arctic waters penetrate the land, even in the smallest gulfs or bays. The lands between Hudson's Bay and Davis' Straits, cut up by water, and the islands in the Arctic Ocean surrounded by water, are intensely cold and destitute of trees—almost of vegetation. The cause of Greenland's being shrouded in ice is its unknown and exceptional extension towards the Pole and the increased height of land in its northern portion. These appear to be necessary conditions of such complete glaciation as we there see, as shown by the absence of an ice-cap in Grinnell and other equally northern lands. The present condition of Greenland is wholly abnormal, and, presenting such unusual conditions, has heightened the astonishment felt when the former mildness of its climate became known.

If we were able to shut off from the Atlantic the enor-

[2] Examples used by De Candolle.
[3] "Physical Geography," p. 312.

[1] "Physical Geography," p. 232.

mous Arctic currents which chill it, we should produce at once a greater increase of heat than is required by the floras. If, further, we impinged the Gulf Stream upon its shores, without cooling it down by floating icebergs upon its back, we might be able to induce at least an even more temperate vegetation to grow there.

Water is thus seen to be the great factor in distributing heat and cold in northern regions, and not land, as has been generally taught. Humboldt believed the rigorous climate of America to be due to high land stretching to the Pole; Lyell taught that with great polar seas and an excess of land at the equator, the hottest conditions possible on the globe would be produced, and that with land at the Poles and a great equatorial sea, the coldest conditions would ensue. A study of the isothermal lines leads to the contrary belief that the presence of land at the Pole, even if ice capped as Greenland is, would be less productive of cold than a polar ocean with free exits, for air has not the distributing power possessed by ocean streams, and when these are ice-laden the effect is still greater.

It only remains to call attention to such proof as we have, that these conditions really did exist in eocene time, and that the Arctic currents were actually shut off from the Atlantic in those days by continuous land which connected the two continents of Europe and North America. In the eocenes of Europe and North America we have evidence of a great, and, comparatively speaking, sudden rise of temperature, and this was followed in due course by a mingling for the first time of the floras and faunas of the two continents. That there was land communication to the north is further evidenced by the occurrence of types of both kinds in the floras now found upon the spots on which they grew. In further support of this theory we have the fact that no trace of sea-deposit of eocene age has ever been found in the polar area, all the vestiges of strata remaining showing that these latitudes were then occupied by dry land.

If we may assume that these conditions really did prevail, and that all the outlets into the Atlantic were closed by the elevation of the present sea-bed between 60° and 70° (where, I believe, the sea is even now shallower) into land of moderate elevation; with or without prolongations south to the 50th latitude; and the north of Greenland submerged, a temperature would ensue more than adequate to support all the plants yet found fossil in eocene or miocene Arctic beds. The result would be that the zone of greatest heat would be far north of the equator; for while the southern hemisphere was still cooled by the Antarctic currents rising to the surface, the North Atlantic would be practically a landlocked sea, cut off from southern cold by the tropics, from northern cold by land, and heated by the sun like the Gulf Stream or Red Sea. There is no need to suppose that the Gulf Stream washed its northern shores, for the temperature would then be raised in excess of what is required, but its aid may be called in to account for the even warmer previous periods evidenced by the older growths of Gleichenia and cycads.

It does not necessarily follow that cold did not then exist towards the Pole. Disko is 20° distant from it, and with an inclosed polar sea we should have a rapid lowering of temperature on the northern shores of the wide belt of land, and might have even a frozen ocean, perhaps as at present, with outlets on the side of Behring's Straits. The assumption that forests stretched to the Poles is not supported by the evidence.

The high temperature in these latitudes would be confined to the Atlantic; and that it was under the same laws as at present seems a reasonable supposition, since the American area even then maintained a relative coolness on account probably of the return and cooler currents being sheared to the west by the rotation of the earth.

To recapitulate. I believe the evidence to be in favour of the eocene age of the Arctic floras in question, and not miocene. I think that the temperature acquired by the plants—especially taking into consideration that their affinities with genera belonging to temperate regions is only inferred upon, in many cases, indistinct fragments—may have been over-estimated. There is no inherent impossibility indeed, that these extinct forms may not be the relics of a flora, like our present Arctic flora, specially adapted to bear a rigorous clime, and colour is lent to this by the abundance of the extinct McClintockia, about whose affinities we know nothing—a flora, perhaps, merely requiring the protecting cover of snow and sea-fog during winter. Finally, I believe that a comparatively slight change in the relative distribution of land and water, such as I have described, would alone account by itself for any fluctuations of temperature, of which we have any record preserved, in, at least, the tertiary rocks.

It does not come within the scope of the present subject, but it is worth consideration, whether wider channels still than those we now possess—some flowing from a more easterly point, so that our land might form the western coast of such a current—would not produce a glacial epoch, intensified by the absence of the Gulf Stream when there was no connecting isthmus (of which there is evidence in recent days) between the two Americas. The present distribution seems, at all events, one productive of more than average cold, as we become aware through the geological record, for the many and wide-existing channels conduct the Arctic waters south, and lower the general temperature of the ocean even to the Tropics.

J. STARKIE GARDNER

ON GAUSSIN'S WARNING REGARDING THE SLUGGISHNESS OF SHIP'S MAGNETISM[1]

Practical Rule and Caution

1. AFTER steering for some time on westerly courses expect—

1. (*a*) Westerly error if you turn to the north;

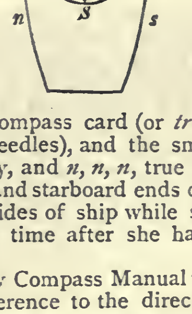
1. (*b*) Or easterly error if you turn to the south.

2. After steering for some time on easterly courses expect—

2. (*a*) Easterly error if you turn to north;

2. (*b*) Or westerly error if you turn to the south.

The diagram representing case 1 (*a*) illustrates the physical explanation, N and S representing the north and



south points of the compass card (or *true south* and *true north* poles of its needles), and the small letters, *s*, *s*, *s*, true southern polarity, and *n*, *n*, *n*, true northern polarity, induced in the port and starboard ends of deck beams and port and starboard sides of ship while steering east, and remaining for some time after she has been turned to north.

In the "Admiralty Compass Manual" Gaussin's warning is given with reference to the direction of swinging, in correcting the compass by magnets according to Airy's

[1] Being an abstract of a Communication by Sir Wm. Thomson, F.R.S., to Section A of the British Association at its last meeting (Dublin).

first method. In the Reports of the Liverpool Compass Committee and in Mr. Towson's "Information for Masters and Mates regarding Ship's Magnetism," instances of perplexing changes in the compass are given, and are referred to the same cause. The "sluggishness" of ship's magnetism, according to which it depends generally in part on the influence experienced some time before the time of observation, and not wholly on the influence at the time, seems to have been first definitely noticed and discussed scientifically by Sir Edward Sabine in his analysis of the results of the magnetic observations in the Antarctic Exploring Expedition of Sir James Ross in the *Erebus* and *Terror*, in the years 1840–41.

The practical rule and caution given above is of great importance in the navigation of iron ships. The amount of the error which may be found cannot be predicted for ships in general, nor for any particular ship except after much experience and careful observation. A small effect of two or three degrees,[1] such as that referred to in the Admiralty Manual as found in M. Gaussin's experience, may be observed in the course of quietly swinging a ship by hawsers or steam-tugs. If the ship under way is steamed round on the different courses the amount of the "Gaussin error" may generally be greater than if she is hauled round by warps; but we must not be sure that it will be so, because the *shake* of the screw which enhances the magnetisation on the east or west courses may shake it out again before the observation is made on the north or south courses.

A good practical rule in correcting the compass is, after having got it quite correct on the north and south courses, correct just half the error which is found after that on the south and north course, in the regular swinging of the ship.

The warning at the head of this article is particularly important for ships of war after firing guns when on easterly or westerly courses; if the course is then changed to north or south, and particularly if, after the firing, the change of course is effected under canvas, without the shaking of the ship's magnetism produced by the engines and screw.

The warning is also very important for ships steaming through the Mediterranean eastwards or westwards, and then turning south through the Suez Canal or north round Cape St. Vincent; and for ships steaming eastwards from America and then turning northwards or southwards into St. George's Channel.

MATHEMATICAL DRAWING INSTRUMENTS[2]

IN his preface the author states that we nowadays expect to find somewhere in print an account of the little mysteries of any particular art, and that partly with the hope of enabling this expectation to be fulfilled, and partly to meet the constant inquiries made respecting certain of the more complicated instruments manufactured by him, he has written his book. The author offers as an apology for any shortcomings in his work, that he is conscious his powers are greater with the lathe and file than in the ways of gentle rhetoric. In our opinion this is unnecessary; we would rather have had the file marks more distinct, and the technical details of construction not so carefully polished out in the work before us as in the well-finished instruments for which the author is so well known. The drawing instruments in most common use, pen, compasses, and dividers, are first described, and the patterns most recommended are illustrated; the type of these instruments now in use seems to meet all requirements, and if of the best quality, appears to require little or no improvement; the needle-point, however, shown on p. 34 (Fig. 1), adapted to compasses or pricker, is an improvement in steadiness on the old form, which was always liable to a little play. The earlier chapters will probably be of use to the beginner in facilitating his choice of the requisite instruments for his work, but he must recollect that dexterity in their use,

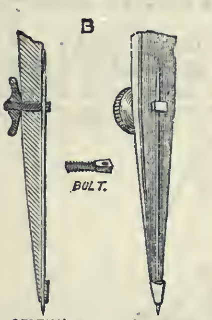


FIG. 1.

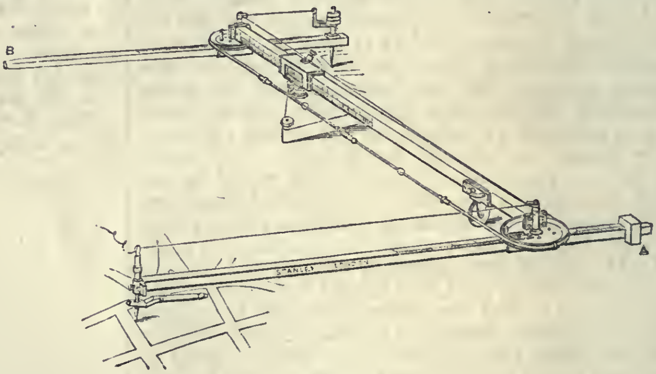

FIG. 2.

even if of the most improved form, can only be acquired with very considerable practice; much time and temper may be saved by the use of good instruments, and there is nothing particularly meritorious in the production of good work with bad instruments if good ones are within his reach.

Of the more complicated instruments next described, some must be regarded rather as mechanical curiosities than of every-day use; others, however, are indispensable where accuracy and the saving of time are of importance; as chief among these we select the eidograph and planimeter. A plan can be reduced or enlarged by dividing it into small squares and filling the details contained in each square into the corresponding squares ruled on the sheet prepared for the copy. This is a tolerably rapid process when the plan is simple in character, and with the help of proportional compasses a good draughtsman may attain considerable accuracy, but for a complicated plan or where great exactness is required, either the pentegraph or eidograph is indispensable. The author justly expresses astonishment at the little use at present made of the eidograph as compared with the pentegraph; the latter as made in this country appears for large work a most clumsy contrivance, offering much unavoidable resistance to motion, and even if made on the most improved Continental pattern is much less handy than the former. The eidograph, as improved by the author, is shown in the cut (Fig 2).

[1] Much greater effects than this are actually found in the cases of gun-practice and of long steaming on easterly or westerly courses referred to below.

[2] "Mathematical Drawing Instruments," by William Ford Stanley. (London: E. and F. N. Spon, 1878.)

The main bar is supported and turns on the pivot carried by the triangular weight; its position with respect to the pivot is adjusted by sliding longitudinally in the box fitted with clamping screw and vernier. On vertical pins at the ends of the main bar turn the two equal pulleys shown; attached to these on their under sides are small boxes also fitted with verniers for the longitudinal adjustment of the two transverse bars. On the similarly situated ends of the transverse bars the tracer and pencil point are carried. When the permanent adjustment of the instrument has been made the transverse arms are parallel, and the pulleys being of equal sizes any rotation given to one communicates an equal rotation to the other by means the flat steel band passing tightly round both; thus the parallelism of the arms is maintained in any position. If now the temporary adjustments are so made that the ratio of the two parts into which the axis of the pivot divides the main beam is equal to ratio of the lengths of the corresponding transverse arms measured from the axes of the pulleys to the pencil and tracer, it is evident that each of those latter is at the apex of a similar triangle, and that the line joining them passes through the axis of the main pivot. Thus the path described by the pencil point is similar to that described by the tracer. The graduations on the bars provides the means of setting the instrument in the required ratio. In the old form the distance between the axes of the pulleys was divided into 200 equal parts, the graduations reading each way from the centre. The transverse arms were made of equal length divided into 200 parts, also reading each way from the centre. For enlargement the setting would be on one side of the centre in each of the three bars and for reducing on the other side. In the improved form shown the tracer and pencil are made interchangeable, and thus the graduation on one half only of each bar is required, while at the same time part of the half arm, B, is dispensed with, making the instrument more handy. In the figure the instrument is set for reducing. The setting is obtained as follows:—Let $\frac{a}{A}$ be the ratio of the scales of the original and reduced plan, and x the reading on the graduations, then for the similar triangles we have $\frac{100 - x}{100 + x} = \frac{a}{A}$, or $x = 100. \frac{A - a}{A + a}$. The chief improvements introduced by the author in the construction of the eidograph consist in making the pencil and tracer interchangeable, which is a considerable simplification, and the introduction of the small roller under the larger arm of the main beam. The improved instrument is stated to be capable of making a reduction down to one-eighth, while the old form certainly became unmanageable at anything beyond one-third.

There is perhaps no instrument whose true value is so little known in the drawing-office as Amsler's Polar Planimeter. The accurate measurement of an area bounded by curved or irregular lines is daily required; and although this can be effected readily and correctly by the aid of the polar planimeter, it is usually laboriously performed by cutting up the area into triangles whose areas are separately determined, or by the measurement of ordinates.

The instrument may be described with the assistance of the figure (Fig. 3). The weight retaining the pin below it at a fixed point, forms the centre about which the more distant arm revolves; to the other extremity of this arm is pivoted a rod carrying a tracing-point at its free extremity. A small roller is mounted on this rod so that its axis is in a line passing through the tracer and pivot at its ends. The roller is provided with a thin projecting edge and is retained in contact with the paper and free to rotate on its axis during any motion given to the instrument. The rotation of the roller is read off from the graduations on its rim by means of a vernier, the number of whole revolutions being shown on the small dial driven by a worm wheel and screw-pinion on the roller-axle. Any motion on the surface of the paper that is given to the point of contact of the roller is resolved into two components, one at right angles to the axis of the roller which is recorded by the dial and vernier readings, and the other parallel to the axis which is a sliding of the roller longitudinally, and is not recorded. To measure the area inclosed by a boundary line as shown in the illustration, the tracing-point is adjusted to any point of the boundary, the dial and wheel are then read off; the tracing-point is then carried round the boundary-line, carefully following it throughout until the starting-point is again reached. The dial and roller are then read off, and the difference of the readings gives the actual area in square inches, or any other units for which the instrument has been graduated. We may now attempt an explanation of the principle of the instrument. Consider first the motion of a straight line parallel to itself. The motion of the centre of the line is compounded of a motion at right angles to it, and one in the direction of its length. The area passed over by the line is equal to its length multiplied by the distance travelled by the centre at right angles to its length.

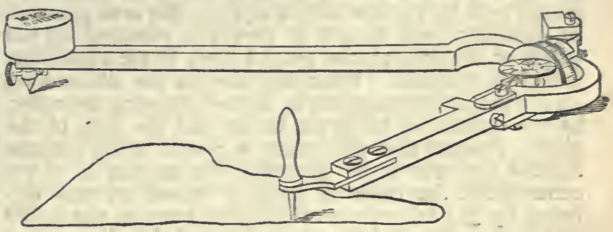

Fig. 3.

If, however, the line be moved, not parallel to itself, but into any other position, it could have been made to reach this position by first moving parallel to itself until its centre reached its new position, and thus, by a rotation of the line about its centre as a fixed point, it could be made to assume the position sought. If a figure representing this be drawn it will be seen that, when the movement is small, the area passed over by the line is approximately equal to its length, multiplied by the perpendicular distance traversed by its centre, as before, and that, when the movement is diminished indefinitely, the area described is in the limit equal to the length multiplied by the perpendicular distance traversed. Now let a roller be mounted at the centre of the line, so as to rotate about it as axis, and let it be so graduated on the rim that the length of one division, multiplied by the length of the line, is equal to a unit of square measure. Then, as the line passes from one position to another, parallel to the plane of the paper, the roller will record the sum of the separate infinitesimal movements of the line at right angles to its length, and will thus, by the graduations on its rim, read off, say, at the point of contact with the paper, give the area passed over by the line. Let $l =$ the length of the line, $\Delta x =$ the perpendicular distance travelled by the roller. Then, in the

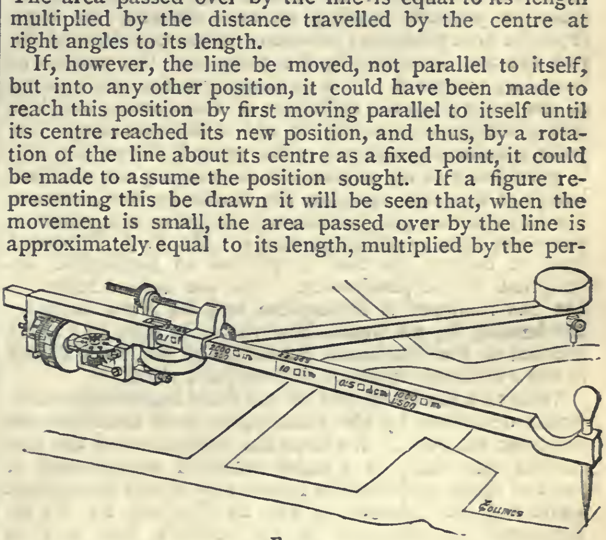

Fig. 4.

limit, $l\,dx =$ the element of area described. In passing over a finite area this will equal $\int l\,dx = lx$, where x is the whole distance recorded by the roller. If now the roller be mounted at a distance r from the centre of the line, in traversing the element of area as before, it will first record $l\,dx$ in its motion parallel to itself, and then, as the line turns about its centre, it will either add or subtract from that reading an amount corresponding to the arc of the circle of radius r, through which it turns; the roller will thus show $l\,dx \pm r\,d\theta$, where $d\theta$ is the small angle turned through. In traversing a finite area this will record $lx \pm r\theta$ where θ is the angle between the initial and final positions of the line. It is now obvious that if the initial and final positions of the line are parallel or coincident, the area passed over by the line will be equal to the area recorded by the roller, even though it were not mounted on the centre of the line, as the second term in the expression just given vanishes. Returning now to the illustration, we see the line represented by the rod carrying the roller, its two extremities being the tracer and the axis of the pivot. Assume that the tracer is placed at the extreme right of the area to be measured: by moving it to the extreme left the roller is made to record an area differing by $\pm r\theta$ from the whole area between the initial and final positions of the rod, and bounded by the portion of the circle described by the further extremity of the rod and by that portion of the boundary of the area traversed, r and θ having the meanings previously assigned to them. Let the tracer be now carried round the boundary back to its starting point on the other side of the area; the roller will now revolve the reverse way, and will subtract from its previous reading an area differing by $\mp r\theta$ from the area contained between the two positions of the rod, the arc described by the pivot and the portion of boundary traversed. It is now apparent that the reading of the roller gives the difference of these areas, which is that of the figure required (Fig. 4).[1] A different form of the polar planimeter is shown in the second illustration, and is provided with an adjustment for varying the effective length of the arm carrying the tracer, by which means the dial and the graduations on the roller are made to show the area to different scales. Mr. F. J. Bramwell was, we believe, the first to publish an intelligible description of the planimeter. This the author refers to, but has rendered it incomplete and far from lucid by condensing it; we would, however, refer him to a short account of the instrument published by Mr. F. P. Purvis in the *Philosophical Magazine* for July, 1874.

With this sketch of two of the most important instruments described by Mr. Stanley, we must conclude our notice of his book. We hope the publication of the new edition may lead to a more extended employment at least of these, and that the favour now shown throughout India and the Colonies, as well as England, for the instruments manufactured by the author's firm may be sufficient inducement to keep them up to their present high standard.

[1] It is here assumed for simplicity sake that the points at which the motion of the roller is reversed are at the extreme right and left of the figure.

NOTES

THE announcement that Dr. W. B. Carpenter is about to retire from the post of Registrar of the University of London will be received with general regret. He has filled the office for twenty-three years.

PROF. MAREY has been elected to fill the place of the late Claude Bernard in the Section of Medicine in the Paris Academy of Sciences.

THE tenth annual report of the U.S. Geological and Geographical Survey of the Territories, in charge of Prof. Hayden, will be ready for distribution in a few weeks. The report has been in type nearly a year, but has been delayed on account of the engraving of the plates. These are now completed and the report will be issued at once. It contains 546 closely printed pages octavo, with eighty plates, sections, maps, &c. Fifty of the plates illustrate the remarkable cliff dwellers in Southern Colorado and Northern New Mexico. This is the last annual report pertaining to Colorado and contains a very interesting series of chapters on the geology of that remarkable country. On the whole this report will prove one of great popular interest and ought to have been published in great numbers. Only 4,500 copies have as yet been ordered. About 250 pages of the eleventh annual report of the field work for 1877 are in type at the Public Printing Office. This will contain a detailed description of the geological and geographical features of Southern Wyoming and Idaho. The reports of Sir Joseph D. Hooker and Dr. Asa Gray will give this volume a high character as well as great popular interest. 10,000 copies have been ordered by Congress. There will be very extended geological reports by Messrs. Endlich, White, St. John, and Peale, and geographical reports by Messrs. Gannett and Wilson, and special reports by Leidy, &c., &c.

VARIOUS items on electric lighting are to hand. It is telegraphed from Washington, December 7, that Mr. Edison's application for a patent for his electric light has been favourably passed by the Patent Office, and that the letters patent were to be issued on Tuesday. The *Journal* of the Society of Arts for December 6 contains a useful *résumé* of the practical application of electricity to lighting purposes, by Mr. J. N. Shoolbred. A new system of electric lamp has been invented in Paris and will be experimented on shortly in public. The carbon rods are four in number, as in the Rapieff system, but instead of crossing at an angle they are arranged in two parallel lines. The consumption of carbon for electric lighting is increasing so rapidly that M. Carré, the well-known Paris maker, is extending his works. He is manufacturing now at the rate of 2,000 meters a day. The electric light illumination has been prolonged, by a vote of the Municipal Council of Paris, up to January 19, for the Avenue de l'Opéra and the front of the Legislative Palace. The city engineers have received orders to prepare, during the interval, a report on the several systems which are now in operation or may be proposed.

THE New York papers report that Mr. Edison has stated that he has made an improved receiver for his telephone by means of which persons standing 15 feet from the instrument can hear a whisper uttered miles away.

AFTER the masterly works of Tschudi on "Animal Life in the Alps," and of Heer on the "History of Vegetation in Switzerland," another work likely to be of high value is announced,—H. Christ on the plants of that country—"Das Pflanzenleben in der Schweiz." The interest of the work is all the greater that Switzerland contains on its narrow area nearly all the diversity of plants which grow in middle and northern Europe. Many years' research of the author in the field, his previous works on separate parts of the Alps, as well as his connection with the botanists of Europe, have enabled Dr. Christ to publish a work which may be expected to range with those above-mentioned. It will appear in four fascicules, with many illustrations, and four maps of vegetable zones, one of which, the distribution of grapes and of several plants of the Föhn and lake regions, will appear this month. The whole work will be finished about the spring of 1879, the first half fascicule having just appeared.

A NEW Botanical Society has just been formed at Munich. the president is Prof. Robert Hartig, and the vice-president Dr. Arnold, an eminent lichenologist.

HERR ALBERT KÜPPERS, an eminent sculptor at Bonn, has

just finished the model of a statue to be erected in memory of Prof. Jacob Nöggerath, the well-known mineralogist.

THE Chinese are about to commence the erection of a line of telegraph from Tientsin to Taku at the mouth of the Pei-ho, and also to make the necessary surveys for another line between Tientsin, Paoting-fu, and Peking.

ACCORDING to the *Colonies and India*, the surveyor, in making a survey of the new road at Mohikinui, in Buller County, New Zealand, struck a coal-seam five feet thick at a distance of only two miles from the township. The coal is bituminous and excellent in quality; it is, moreover, easily accessible and can be brought to the port at a very small cost.

THE Council of the Society of Arts have addressed a memorial to Lord Salisbury asking him to request her Majesty's Ministers abroad to collect information on the system of technical and industrial education in foreign countries, in continuation of what was published in 1868. Lord Salisbury has promised to give the matter his consideration, though we think this is rather an unfortunate time to address the Foreign Secretary on so peaceful a subject.

IN reference to the statement that Sir William Armstrong has employed electricity, generated by water power, a mile and a half distant, to light his picture gallery, and that he proposes to use the same force to turn machinery about his house, Mr. D. R. Jones sends us a copy of a letter sent by him to the *Australasian*, October 25, 1870, in which, referring to the phenomena of dynamic electricity, he states that it is evident that motion may be transformed into electricity, and *vice versâ*. He suggests that we may have here "the means of utilising the motions of the air and of water, which, for want of means of transmission, have been hitherto allowed to run to waste. Various methods of converting, transmitting, and utilising force will readily suggest themselves as a combination of these well-known facts. While we have such superabundant constant supplies of force it is not right that the stores of Nature should be ransacked."

THE *Times* of Monday contains another letter from Dr. Schliemann, giving an account of his further excavations on the site of Troy. He has succeeded in exploring much of the remains of the ancient structures so that the plan can be very distinctly traced. Dr. Schliemann himself left London on Monday for Paris, and intends to recommence work on March 1. A number of the objects found during the last explorations have been deposited in the South Kensington Museum, where they will be exhibited.

THE *Midland Naturalist*, we are glad to see, has concluded a successful first volume. Its past twelve numbers contain many papers of value, both on local and general scientific matters, and its conduct is creditable to its editors and to the many societies of which it is the organ. The December number contains a carefully compiled index, which must be a great comfort to those in search of any paper or subject in the volume. Several good contributions are promised for the next volume, and we trust that the journal will receive every encouragement from the members of the societies it represents, and that its conductors will strive to make it thoroughly representative of the science of the Midlands.

A CORRESPONDENT "R. C. J.," writes as follows from Driefontein, Heilbronn District, Orange Free State, South Africa, under date October 14:—"Our last winter was dry throughout, and unusually cold, that is, June, July, and August, and on August 3 a piece of country in the Transvaal, about seventy or eighty miles north of this part, and on the road from this to Pretoria, about fifteen or twenty miles wide, and perhaps the same in length, was visited in twenty-four hours with such a sudden change of temperature, from 85° to 42° F., that more than 100 bodies of dead Kafirs, besides oxen, were found as if killed by the sudden abstraction of caloric. There was no wind or rain, but a fall of snow. The land is about as high as this, about 4,600 feet."

EXCAVATIONS are now in progress on the Limburg, in the Bavarian palatinate, which will lead to important results for prehistoric investigation, inasmuch as they are directed to the elucidation of the much contested question regarding the constructors and former inhabitants of the Ringwall near Dürkheim.

La Semaine Française is the title of a new weekly French paper published in London for English readers, and which is meant to appeal "to all those who wish to read good French in the way in which it is most likely to be read with interest and profit." The number before us is well selected as to contents, and contains news of French matters and expressions of French opinion in various departments. A small amount of space, we are pleased to see, is devoted to science.

DR. RAE writes that at about 14m. past midnight of December 5–6, whilst there was bright moonlight, he observed a meteor of intensely bright and white light passing obliquely downwards from west to east. It was first noticed almost directly below the western foot of Orion, and disappeared when slightly to eastward of Sirius, having passed at 3° or 4° of arc below these stars. It was spherical and apparently of 6′ or 8′ diameter, with a fiery red tail four or five times that length.

AN earthquake occurred in Scotland on Tuesday morning last week at Balnacara and other parts of the district of Loch Alsh, on the west coast of the county of Ross, opposite the Isle of Skye. The shock was very marked, the tremulous motion of the earth being distinctly felt, and the houses shaking violently At Balnacara the shock occurred at 5 o'clock, and at Plocton, five miles distant, between 7 and 8.

AN Indian paper states that in the Ferozepore district the rise of the Sutlej has once more broken the head-works of the inundation canals, and over 100 square miles of country are under water. The damage done to property has been great, but on the other hand a quantity of treasure has been uncovered by the floods in the old fort of Momdote, a few miles from Ferozepore.

MR. CORNELIUS WALFORD has reprinted in a separate form his elaborate and valuable paper on "The Famines of the World, Past and Present," read in March last before the Statistical Society.

THE Eleventh Annual Report of the Trustees of the Peabody Museum of American Archæology and Ethnology to the President and Fellows of Harvard College is an unusually interesting one. The description of the new museum buildings at Cambridge is very full, and illustrated with plans and a photographic view; the building seems admirably adapted to the purpose for which it is intended. Besides an account of the additions to the Museum and the work done since the last Report, the present publication contains the following papers:—"Second Report on the Implements found in the Glacial Drift of New Jersey," by Dr. C. C. Abbot; "The Method of Manufacture of several Articles by the former Indians of South Carolina," by Mr. Paul Schumacher; "Cave Dwellings in Utah," by Mr. Edward Palmer; "Notes on a Collection from an Ancient Cemetery in Southern Peru," by Mr. J. H. Blake; "Archæological Explorations in Tennessee," by Mr. F. W. Putnam (this long and amply illustrated paper is separately reprinted); "Observations on the Crania from the Stone Graves in Tennessee," by Mr. Lucien Carr; "On the Tenure of Land Among the Ancient Mexicans," by Mr. A. F. Bandelier. Besides Mr. Putnam's paper most of the others are accompanied by numerous illustrations.

In a note on "Colonial Grasses as Paper-making Materials," the *Colonies and India* suggests the possibility of utilising some of the coarse grasses which grow with such provoking pertinacity in South Africa, Australia, New Zealand, &c. The *Typha angustifolia*, for example, a large kind of tussock grass (known as *raupo* to the New Zealand natives, who use it for thatching their houses), which grows in enormous quantities in the swampy flats near rivers and lakes, may, like its neighbour, the *Phormium tenax*, prove a rival to Esparto grass; the *wiwi*, a coarse, wiry kind of grass, growing chiefly in the interior of North Island, is also worth an experiment. In New South Wales the grass-cloth plant (*Böhmeria nivea*) has already received some attention, being used for the manufacture of a fine kind of matting. South Africa is probably richest of all in its grasses; in the great Karroo district thousands of square miles are covered with the twaa-grass, the sour-veldt, and the sweet-veldt, the importance of which as fodder may be found equalled by their value as paper-making material. Still more likely to prove valuable is the *Stipa capensis*, a member of the family to which Esparto belongs.

The *Transactions* of the Cumberland Association for the Advancement of Literature and Science, Part III., 1877-78, edited by Mr. Clifton Ward, is a thickish volume containing papers by members of some of the Associated Societies. The first paper, however, after various reports, is that by Sir George Airy, on the "Probable Condition of the Interior of the Earth," a report of which we gave at the time of its delivery; accompanying it is a diagram of an ideal earth. Mr. Ward has a paper on "Quartz in the Lake District;" Mr. C. Smith one on "Boulder Clay;" Mr. Pickering, on a "Submerged Forest at St. Bees;" and Mr. Fisher Crosthwaite gives an interesting account of Peter Crosthwaite, who, at the end of the last and beginning of the present centuries, did much to promote science in the district.

M. J. Poliakoff, who was sent last summer by the St. Petersburg Academy of Sciences to examine the remains of the stone period in the governments of Yaroslaff and Vladimir, gives the following results of his explorations:—Very interesting collections were found in excavating a mound, close by Yaroslaff; numerous skulls of men of the neolithic period were discovered here, together with polished silex hatchets and hammers, and numerous bones of animals of existing species. Far richer collections were found in the valley of the Oka River, in the district of Murom. Here, in the sandy mounds of the valley, as well as in the alluvium of the river, M. Poliakoff has discovered immense quantities of silex implements, polished and rough, of the most varied forms. The implements were always found together with bones of the *Castor fiber*, the *Sus scrofa ferus*, and the *Bos primigenius*, none of which exist now in those regions. Besides, he also discovered vestiges of old wood buildings, very like the lacustrian dwellings of Switzerland. The most important discovery during these explorations was made by M. Poliakoff, in company with Count Uraroff, close by Karacharovo Town, in a very old lake alluvium, being a somewhat washed-up glacier deposit. Here they found rough stone implements of the paleolithic period, together with bones of the mammoth, rhinoceros, and the *Bos priscus*. The character of the deposits proved without doubt the co-existence of man with those extinct mammals in Russia, as well as in other parts of Europe. After having finished his explorations, M. Poliakoff made a journey in Western Europe to study the chief museums, and to compare the implements he has collected during many years in Russia and Siberia, Western and Eastern, with those of England, Sweden, Denmark, France, and Switzerland. We expect that this last journey of M. Poliakoff will accelerate the opening of the projected pre-historic museum at St. Petersburg.

The additions to the Zoological Society's Gardens during the past week include two Black-faced Spider Monkeys (*Ateles ater*), two Rufous-vented Guans (*Penelope cristata*) from U. S. of Columbia, two Horsfield's Tortoises (*Testudo horsfieldi*) from Turkestan, presented by Mr. A. Gonzalez Carazo; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. A. G. Lytton Squires; two Black-eared Marmosets (*Hapale penicillata*) from South-East Brazil, presented by the Countess of Cotterham; two Laughing Kingfishers (*Dacelo gigantea*) from Australia, presented by Mr. Edwin A. B. Crockett; a Ceylon Jungle Fowl (*Gallus stanleyi*) from Ceylon, two Japanese Pheasants (*Phasianus versicolor*) from Japan, a Grey Francolin (*Francolinus ponticerianus*) from India, presented by Mr. Geo. Lyon Bennett; a Rhomb-marked Snake (*Psammophylax rhombeatus*), three Rufescent Snakes (*Leptodira rufescens*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Kinkajou (*Cercoleptes caudivolvulus*) from South America, three Snow Buntings (*Plectrophanes nivalis*), European, purchased.

ROYAL SOCIETY—THE PRESIDENT'S ANNIVERSARY ADDRESS[1]

II.

The modern development of botanical science, being that which occupies my own attention, is naturally that on which I might feel especially inclined to dwell; and I should so far have the excuse that there is, perhaps, no branch of research with the early progress of which this Society is more intimately connected.

One of our earliest secretaries, Robert Hooke, two centuries ago, laboured long and successfully in the improvement of the microscope as an implement of investigation. He was one of the first to reap the harvest of discovery in the new fields of knowledge to which it was the key, and if the results which he attained have rather the aimless air of spoils gathered hither and thither in a treasury, the very fulness of which was embarrassing, we must remember that we date the starting-point of modern histology from the account given by Hooke in his "Micrographia" (1667) of the structure of cork, which had attracted his interest from the singularity of its physical properties. Hooke demonstrated its *cellular structure*, and by an interesting coincidence he was one of the first to investigate, at the request, indeed, of the founder of the Society, Charles II., the movement of the sensitive plant *Mimosa pudica*, one of a class of phenomena which is still occupying the attention of more than one of our Fellows. In attributing the loss of turgescence, which is the cause of the collapse of the petiole and subordinate portions of the compound leaf which it supports, to the escape of a subtle humour, he to some extent foreshadowed the modern view which attributes the collapse of the cells to the escape of water by some mechanism far from clearly understood —whether from the cell-cavities or from the cell-walls into the intercellular spaces.

Hooke having shown the way, Nehemiah Grew, who was also secretary of the Royal Society, and Marcello Malpighi, Professor of Medicine in the University of Bologna, were not slow to follow it. Almost simultaneously (1671–3) the researches of these two indefatigable students were presented to the Royal Society, and the publication of two editions of Malpighi's works in London prove how entirely this country was at that time regarded as the head-quarters of this branch of scientific inquiry. We owe to them the generalisation of the cellular structure, which Hooke had ascertained in cork, for all other vegetable tissues. They described also accurately a host of microscopic structures then made known for the first time. Thus, to give one example, Grew figured and described in several different plants the stomata of the epidermis:—"Passports either for the better avolation of superfluous sap, or the admission of air."

With the exception of Leeuwenhoek no observer attempted to make any substantial addition to the labours of Grew and Malpighi for more than a century and a half, and however remarkable is the impulse which he gave to morphological studies, the view of Caspar Wolff in the middle of the eighteenth cen-

[1] Address of Sir Joseph Hooker, C.B., K.C.S.I., the President, delivered at the Anniversary Meeting of the Royal Society, on Saturday, November 30, 1878. Continued from p. 113.

tury (1759), in regarding cells as the result of the action of an organising power upon a matrix, and not as themselves influencing organisation, were adverse to the progress of histology. It is from Schleiden (1838), who described the cell as the true unit of vegetable structure, and Schwann, who extended this view to all organisms whether plants or animals, and gave its modern basis to biology by reasserting the unity of organisation throughout animated nature, that we must date the modern achievements of histological science. Seldom, perhaps, in the history of science has any one man been allowed to see so magnificent a development of his ideas in the space of his own lifetime as has slowly grown up before the eyes of the venerable Schwann, and it was, therefore, with peculiar pleasure that a letter of congratulation was intrusted by the officers to one of the Fellows of this Society on its behalf on the recent occasion of the celebration of the fortieth anniversary of Schwann's entry into the professoriate.

If we call up in our mind's eye some vegetable organism and briefly reflect on its construction, we see that we may fix on three great steps in the analysis of its structure, the organic, the microscopic, and the molecular, and, although not in the same order, each of the three last centuries is identified with one of these. In the seventeenth century Grew achieved the microscopic analysis of plant tissues into their constituent cells; in the 18th, Caspar Wolff effected the organic analysis (independently but long subsequently expounded by the poet Goethe) of plant structures into stem and leaf. It remained for Nägeli in the present century to first lift the veil from the mysterious processes of plant growth, and by his memorable theory of the molecular constitution of the starch-grain and cell-wall, and their growth by intussusception (1858), to bring a large class of vital phenomena within the limits of physical interpretation. Strasburger has lately (1876) followed Sachs in extending Nägeli's views to the constitution of protoplasm itself, and there is now reason to believe that the ultimate structure of plants consists universally of solid molecules (not, however, identical with chemical molecules) surrounded with areas of water which may be extended or diminished. While the molecules of all the inert parts of plants (starch-grains, cell-wall, &c.) are on optical grounds believed to have a definite crystalline character, no such conclusion can be arrived at with respect to the molecules of protoplasm. In these molecules the characteristic properties of the protoplasm reside, and are more marked in the aggregate mass in proportion to its denseness, and this is due to the close approximation of the molecules and the tenuity of their watery envelopes. The more voluminous the envelopes the more the properties of protoplasm merge in those of all other fluids.

It is, however, to the study of the nuclei of cells that attention has been recently paid with the most interesting results. These well-known structures, first observed by Ferdinand Bauer at the beginning of the century (1802), were only accurately described, thirty years later, by Robert Brown (1833). Up to the present time their function has been extremely obscure. The beautiful investigations of Strasburger (1875) have led him to the conclusion that the nucleus is the seat of a central force which has a kind of polarising influence upon the protoplasm molecules, causing them to arrange themselves in lines radiating outwards. Cell-division he regards as primarily caused by the nucleus becoming bipolar, and the so-called caryolitic figures first described by Auerbach exhibit the same arrangement of the protoplasm molecules in connecting curves as in the case of iron-filings about the two poles of a bar-magnet. The two new centres mutually retire, and each influencing its own tract of protoplasm, the cell-division is thereby ultimately effected. This is but a brief account of processes which are greatly complicated in actual detail, and of which it must be remarked that, while the interest and beauty of the researches are beyond question, caution must be exercised in receiving the mechanical speculations by which Strasburger attempts to explain them. He has himself shown that cell-division presents the same phenomena in the animal kingdom, a result which has been confirmed by numerous observers, amongst whom I may content myself with mentioning one of our own number, Mr. F. Balfour. Strasburger further points out that this affords an argument for the community of descent in animal and vegetable cells; he regards free cell-division as derivable from ordinary cell-division by the suppression of certain stages.

Turning now to the discoveries made during the last five years in physiological botany, we find that no one has advanced this subject so greatly as Mr. Darwin. In 1875 was published his work on insectivorous plants, in which he ascertained the fact that a number of species having elaborate structures adapted for the capture of insects, utilised the nitrogenous matter which these contain as food. The most important principle established in the course of these researches was that such plants as *Drosera*, *Dionæa*, *Pinguicula*, &c., secrete a digestive fluid, which has led, through Gorup Bezanez's investigations on the ferment in germinating seeds, to a recognition of the active agency of ferments in the transmission of food-material, which marks a great advance in our knowledge of the general physiology of nutrition.

The extreme sensitiveness of the glands of *Drosera* to mechanical and chemical stimulus (especially to phosphate of ammonia), the directive power of its tentacles, depending upon the accurate transmission of motor impulses, and the "reflex" excitation of secretion in the glands, were all discoveries of the most suggestive nature in connection with the subject of the irritability and movements of plants. The phenomenon of the aggregation of the protoplasmic cell-contents in the tentacles of *Drosera* is a discovery of a highly remarkable nature, though not yet thoroughly understood. Lastly, Mr. Frank Darwin, following his father's footsteps, as it were crowned the edifice by showing to what an extent insectivorous plants do profit by nitrogenous matter supplied to their leaves.

In close relation to these researches are those, also by Mr. Darwin, on the structure and functions of the bladder of *Utricularia*, which he has shown to have the power of absorbing decaying animal matter; and those of Mr. Frank Darwin on contractile filaments of extraordinary tenuity attached to the glands on the inner surface of the cups formed by the connate bases of the leaves of the teasel, and which filaments exhibit motions suggesting a protoplasmic origin. It is to be hoped that their discoverer will pursue his investigations upon these curious bodies, whose origin and real nature in relation to the plant and its functions is involved in obscurity.

The subject of the cross-fertilisation of plants, which, though a long-known phenomenon, first become a fruitful scientific study in Mr. Darwin's now classical work, "On the Various Contrivances by which Orchids are Fertilised," has within the last few years made rapid advance under its author's hand. The extreme importance of avoiding self-fertilisation might indeed be inferred from the prevalence in flowers of elaborate contrivances for preventing it; but it remained to be shown that direct benefit attended cross-fertilisation, and this has now been proved by an elaborate series of experiments, the results of which are not only that both increased fertility or greater vigour of constitution attend cross-fertilisation, but that the opposite effects attend self-fertilisation. In the course of these experiments it became evident that the good effects of the cross do not depend on the mere fact of the parents being different individuals, for when these were grown together and under the same conditions, no advantage was gained by the progeny; but when grown under different conditions a manifest advantage was gained. As instances, if plants of *Ipomœa* and *Mimulus*, which had been self-fertilised for seven previous generations, were kept together and then intercrossed, their offspring did not profit in the least; whereas, when the parent plants were grown under different conditions, a remarkably vigorous offspring was obtained.

Mr. Darwin's last work, "On the Different Forms of Flowers," though professedly a reprint of his paper on dimorphic plants, published by the Linnean Society, contains many additions and new matter of great importance in reference to the behaviour of polygamous plants, and on cleistogamic flowers. Among other points of great interest is the establishment of very close analogies between the phenomena attending the illegitimate union of trimorphic plants and the results of crosses between distinct species: the sterile offspring of the crosses of the same species exhibiting the closest resemblance to the sterile hybrids obtained by crossing distinct species; while a whole series of generalisations, founded on the results of the one series of experiments, are closely paralleled by those founded on the other. The bearing of this analogy on the origin of species is obviously important.

Besides these investigations, Mr. Darwin has produced within the last five years second editions of his volume on the "Fertilisation of Orchids," and on the "Habits and Movements of Climbing Plants," as also of his early works on "Coral Reefs," and "Geological Observations in South America;" all of them abounding in new matter.

Of special interest to myself, as having been conducted in the

Jodrell Laboratory at Kew, are Dr. Burdon Sanderson's investigations on the exceptional property possessed by the leaves and other organs of some plants which exhibit definite movements in response to mechanical, chemical, or electric stimuli. In 1873 this physiologist showed us in our meeting-room that the closing of the laminæ of the leaf of *Dionæa* is preceded by a preliminary state of excitement, and is attended with a change in the electric conditions of the leaf; and this so closely resembled the change which attends the excitation of the excitable tissues of animals that he did not hesitate to identify the two phenomena.

This remarkable discovery immediately directed the attention of two German observers to the electromotive properties of plants, one, Dr. Kunkel, in the laboratory of Prof. Sachs; the other, Prof. Munk, in that of the University of Berlin.

Prof. Munk, whose researches are of much the greater scope and importance, took as his point of departure Dr. Burdon Sanderson's discovery. The leading conclusion to which he arrived was that in *Dionæa* each of the oblong cells of the parenchyma is endowed with electromotive properties which correspond with those of the "muscle-cylinder" of animals; with this exception, that whereas in the muscle-cylinder the ends are negative to the central zone, in the vegetable cell they are positive; and he endeavours to prove that according to this theory all the complicated electromotive phenomena which had been observed could be shown to be attributable to the peculiar arrangement of the leaf-cells.

During the last two summers Dr. Burdon Sanderson has been engaged in endeavouring to discover the true relations which subsist between the electrical disturbance followed by the shutting of the leaf-valves of *Dionæa* and the latent change of protoplasm which precedes this operation. He has found that though the mechanism of the change of form of the excitable parenchyma which causes the contraction is entirely different from that of muscular contraction, yet that the correspondence between the exciting process in the animal tissues and what represents this in plant tissues appears to be more complete the more carefully the comparison is made; and that whether the stimulus be mechanical, thermal, or electrical, its effects correspond in each case. Again, the excitation is propagated from the point of excitation to distant points in the order of their remoteness, and the degree to which the structure is excited depends upon its temperature. Notwithstanding, however, the striking analogies between the electrical properties of the cells of *Dionæa* and of muscle-cylinders, Dr. Burdon Sanderson is wholly unable to admit with Prof. Munk that these structures are in this respect comparable.

In morphological botany attention has been especially directed of late to the complete life-history of the lower order of cryptogams, since this is seen to be more and more an indispensable preliminary to any attempt at their correct classification.

The remarkable theory of Schwendener, now ten years old, astonished botanists by boldly sweeping away the claims to autonomous recognition of a whole group of highly characteristic organisms—the lichens—and by affirming that these consist of ascomycetal fungi united in a commensal existence with algæ. The controversial literature and renewed investigations which this theory has given rise to is now very considerable. But the advocates of the Schwendenerian view have gradually won their ground, and the success which has attended the experiments of Stahl in taking up the challenge of Schwendener's opponents, and manufacturing such lichens as *Endocarpon* and *Thelidium*, by the juxtaposition of the appropriate algæ and fungi, may almost be regarded as deciding the question. Sachs, in the last edition of his "Lehrbuch," has carried out completely the principle of classification of algæ, first suggested by Cohn, and has proposed one for the remaining thallophytes, which disregards their division into fungi and algæ. He looks upon the former as standing in the same relation to the latter as the so-called saprophytes (*e.g. Neottia*) do to ordinary green flowering-plants.

This view has especial interest with regard to the minute organisms known as *Bacteria*, a knowledge of the life-history of which is of the greatest importance, having regard to the changes which they effect in all lifeless and, probably, in all living matter prone to decomposition. This affords a morphological argument (as far as it goes) against the doctrine of spontaneous generation, since it seems extremely probable that just as yeast may be a degraded form of some higher fungus, *Bacteria* may be degraded allies of the *Oscillatoriæ*, which have adopted a purely saprophytal mode of existence.

Your *Proceedings* for the present year contain several important contributions to our knowledge of the lowest forms of life. The Rev. W. H. Dallinger, continuing those researches which his skill in using the highest microscopic powers and his ingenuity in devising experimental methods have rendered so fruitful, has adduced evidence which seems to leave no doubt that the spores or germs of the monad which he has described differ in a remarkable manner from the young or adult monads in their power of resisting heated fluids. The young and adult monads, in fact, were always killed by five minutes' exposure to a temperature of 142° F. (61° C.), while the spores germinated after being subjected to a temperature of 10° above the boiling-point of water (222° F.).

Two years ago, Cohn and Koch observed the development of spores within the rods of *Bacillus subtilis* and *B. anthracis*. These observations have been confirmed, with important additions, in these two species by Mr. Ewart, and have been extended to the *Bacillus* of the infectious pneumo-enteritis of the pig, by Dr. Klein; and to *Spirillum* by Messrs. Geddes and Ewart; and thus a very important step has been made towards the completion of our knowledge of the life-history of these minute but important organisms. Dr. Klein has shown that the infectious pneumo-enteritis, or typhoid fever of the pig, is, like splenic fever, due to a *Bacillus*. Having succeeded in cultivating this *Bacillus* in such a manner as to raise crops free from all other organisms, Dr. Klein inoculated healthy pigs with the fluid containing the *Bacilli*, and found that the disease in due time arose and followed its ordinary course. It is now, therefore, distinctly proved that two diseases of the higher animals, namely, "splenic fever" and "infectious pneumo-enteritis," are generated by a *contagium vivum*.

Finally, Messrs. Downes and Blunt have commenced an inquiry into the influence of light upon *Bacteria* and other *Fungi*, which promises to yield results of great interest, the general tendency of these investigations leaning towards the conclusion that exposure to strong solar light checks and even arrests the development of such organisms.

The practical utility of investigations relating to *Bacillus* organisms as affording to the pathologist a valuable means of associating by community of origin various diseases of apparently different character, is exemplified in the "Loodiana fever," which has been so fatal to horses in the East. The dried blood of horses that had died of this disease in India has been recently sent to the Brown Institution, and there afforded seed from which a crop of *Bacillus anthracis* has been grown, which justified its distant pathological origin by reproducing the disease in other animals. Other equally interesting experiments have been made at the same Institution, showing that the "grains" which are so largely used as food for cattle, afford a soil which is peculiarly favourable for the development and growth of the spore filaments of *Bacillus;* and that by such "grains" when inspected, the anthrax fever can be produced at will, under conditions so simple, that they must often arise accidentally. The bearing of this fact on a recent instance in which anthrax suddenly broke out in a previously uninfected district, destroying a large number of animals, all of which had been fed with grains obtained from a particular brewery, need scarcely be indicated.

In systematic botany, which, in a nation like ours, that is ever extending its dominions and exploring unknown regions of the globe, must always absorb a large share of the energies of its phytologists, I can but allude to two works of great magnitude and importance.

Of these the first is the "Flora Australiensis" of Bentham, completed only a year ago; a work which has well been called unique in botanical literature, whether for the vast area whose vegetation it embraces (the largest hitherto successfully dealt with), or for the masterly manner in which the details of the structure and affinities of upwards of 8,000 species have been elaborated; its value in reference to all future researches regarding the geographical distribution of plants, the southern hemisphere, and the evolution therein of generic and specific types, cannot be over-estimated.

The other great work is the "Flora Braziliensis," commenced by our late foreign Fellow, von Martius, and now ably carried on by Eichler, of Berlin, assisted by coadjutors (amongst whom are most of our leading systematists) under the liberal auspices of His Majesty the Emperor of Brazil. When completed, this gigantic undertaking will have embraced, in a systematic form, the vegetation of the richest botanical region of the globe.

Having now endeavoured to recall to you some of the great advances in science made during the last few years, it remains for me, after the distribution of the medals awarded by your Council, to retire from the Presidency in which I have so long experienced the generous support of your officers and yourselves. This support, for which I tender you my hearty thanks, together with my sense of the trust and dignity of the office, and the interest attached to its duties, has rendered my resignation of it a more difficult step than I had anticipated. My reasons are, however, strong. They are the pressure of official duties at Kew, which annually increase in amount and responsibility, together with the engagements I am under to complete scientific works, undertaken jointly with other botanists, before you raised me to the Presidency, and the indefinite postponement of which works delays the publication of the labours of my coadjutors. I am also influenced by the consideration that, though wholly opposed to the view that the term of the Presidency of the Royal Society should be either short or definitely limited, this term should not be very long; and that, considering the special nature of my own scientific studies, it should, in my case, on this as well as on other grounds, be briefer than might otherwise be desirable. Cogent as these reasons are they might not have been paramount were it not that we have among us one pre-eminently fitted to be your President by scientific attainments, by personal qualifications, and by intimate knowledge of the Society's affairs; and by calling upon whom to fill the proud position which I have occupied, you are also recognising the great services he has rendered to the Society as its treasurer for eight years, and its ofttimes munificent benefactor.

HAECKEL ON THE LIBERTY OF SCIENCE AND OF TEACHING[1]

II.

CHAPTER V. treats of the methods of teaching, and contrasts the *genetic* method, as advocated by Haeckel, with the *dogmatic* one recommended by Virchow. The sensation which Virchow's address caused in wider circles was only partly the result of his opposition to the descent theory; its principal cause was his surprising conclusions with regard to the liberty of teaching. Virchow demands that in the school—from the elementary school up to the university—*nothing should be taught which is not absolutely certain*; only *objective* but no *subjective* knowledge is to be communicated to the pupils by the teacher; only facts, no hypotheses. Haeckel remarks that rarely has an eminent representative of science made such an attack upon the liberty of science as did Virchow at Munich. "Where," he asks, "are we to find the limits between subjective and objective knowledge?" According to his conviction no such limit exists, and all human knowledge as such is subjective. "An objective science consisting only of facts, without subjective theories, cannot be imagined." He then proceeds to review various sciences in turn, and to point out how much objective knowledge and "facts," and how much subjective knowledge and "hypotheses" they contain. He begins with *Mathematics* as the science which is eminently the most *certain* one of all: "What about the simplest and deepest maxims upon the firm basis of which the whole proud building of mathematics rests? Can they be proved for certain? Certainly not! The most fundamental maxims are indeed 'maxims,' and incapable of 'proof.' Only in order to show by an example how even the first mathematical maxims may be attacked by sceptics and shaken by philosophical speculation we recall the recent discussions regarding the three dimensions of space and the possibility of a fourth dimension, discussions which are still continued by a number of the most illustrious mathematicians, physicists, and philosophers. So much is certain that mathematics is absolutely objective as little as any other science, but has a subjective basis in man's own nature. . . . But even if we own that mathematics is an absolutely certain and objective science, how about all other sciences? No doubt those are 'most certain' amongst the 'exact' sciences, the maxims of which are founded on pure mathematics, in the first line therefore a great part of *physics*. We say a great part, because another great part—upon close examination by far the greater—is incapable of an exact mathematical foundation. Or what we do know with certainty about the essence of *matter* or the essence of *force?* What do we know for certain about gravitation, about mass-attraction, about action at a distance, &c.? We look upon Newton's gravitation theory, the basis of mechanics, as the most important and most certain theory of physics, and yet gravitation itself is only a hypothesis. And then the other branches of physics—electricity and magnetism, for instance. The whole knowledge of these important branches is based upon the hypothesis of 'electric fluids' or of imponderable substances, the existence of which is certainly not proved. Or optics? No doubt optics belongs to the most important and most complete branches of physics, yet the vibration theory, which to-day we consider to be its indispensable basis, rests upon a hypothesis which cannot be proved, viz., upon the 'subjective' supposition of the light-ether, the existence of which nobody can objectively prove. Nay, even more; before Young established the vibration theory of light, the emanation theory taught by Newton reigned supreme in physics for centuries; this theory has to-day been abandoned as untenable. According to our view the mighty Newton acquired the greatest merit with regard to the development of optics, as he made the first attempt to connect and explain the mass of objective optical facts by a subjective leading hypothesis. But according to Virchow's view Newton sinned most heavily by teaching this false hypothesis; because in 'exact' physics only *single* and *certain facts* are to be taught and to be ascertained by 'experiment as the highest means of proof;' but physics as a *whole*, resting as it does upon a number of unproved hypotheses, may be the object of research, but must not be taught!" Turning to *Chemistry*, Haeckel shows that its objectiveness stands upon still weaker feet than that of physics. Here the whole of the science is built upon the hypothesis of the existence of atoms, a hypothesis as unproved and as incapable of proof as any. No chemist has ever seen an atom, and yet he thinks the mechanics of atoms the highest problem of his science, and describes and constructs the positions and groupings of atoms, as if they were before him on his dissecting table. According to Virchow, we therefore ought *to banish chemistry from the school* and teach only the properties of bodies and their reactions, which can be shown to the pupils as "certain facts." This matter becomes still more ludicrous when we turn to the other sciences, which are all more or less *historical*, and therefore do not possess that "half-exact" basis upon which chemistry and physics rest. Geology, for instance, would, according to Virchow, have to confine itself to the description of certain facts, *i.e.*, the structure of rocks, the forms of fossils, the shape of crystals, &c., but would in the school have completely to abandon all speculation regarding the development of the earth's crust, *i.e.*, nothing but unproved hypotheses from beginning to end. We might not even teach that fossils are the actual remains of organisms which existed in former periods, because even this is an "unproved" hypothesis. Even down to the eighteenth century many eminent naturalists believed fossils to be "freaks of nature," an enigmatic "*lusus naturæ*." In a later part of his address Virchow admits fossils as "objective material proofs;" but even here we may go no further than our actual experience allows, and we may not draw subjective deductions from the objective facts. Virchow's remark about quaternary man being an "accepted fact" affords Haeckel an opportunity for pointing out his inconsistency, and the uncertainty and vagueness of most hypotheses concerning the age and the first geological occurrence of man; indeed, the distinction of a tertiary and a quartery age in itself is nothing but a *geological hypothesis*. "Virchow tells us that never has a fossil ape skull been found which really belonged to a human proprietor, and that we cannot consider it as a revelation of science, we cannot teach, that man descends from the ape or from any other animal. If that be true, then nothing remains but the descent from a god or from a clod of earth."

Zoology, botany, and other biological doctrines do not fare better, if we consider them in the light in which Virchow would have them taught. Haeckel shows the utter untenability of Virchow's demands, since no science, not even history, and certainly not philosophy, could be tolerated in our schools; indeed, the only one which could remain would be theology. "Incredible as it seems, Virchow, the sceptical antagonist of dogmas, the combatant for the liberty of science, now finds the only certain basis of instruction in the dogma of Church religion. After all that has happened the following phrase leaves no doubt on this point:—'All attempts to transform our problems into doctrines, to introduce our theories as the basis of a plan of education, par-

[1] Freie Wissenschaft und freie Lehre. Eine Entgegnung auf Rudolf Virchow's Münchener Rede über "die Freiheit der Wissenschaft im modernen Staat." Von Ernst Haeckel. Continued from p. 115.

ticularly the attempt simply to depose the Church, and to replace its dogma by a religion of descent without further trouble—these attempts, I say, must fail, and their failure would at the same time bring the greatest dangers upon the position of science generally.' After this every one will easily understand the joyful outbursts of the whole clerical press after Virchow's Munich address. It is known that there is ten times more joy in heaven over one repentant sinner than oven ten just men. If Rudolf Virchow, the 'renowned materialist,' the 'radical progressist,' the principal representative of the 'atheism of science,' is suddenly so completely converted, if openly and loudly he proclaims the 'dogmas of the Church' as the only certain 'basis of instruction,' then, indeed, the combatant Church may sing 'Hosanna in excelsis!' There is only one point to be regretted, and that is that Virchow has not stated which of the many different Church religions is the only true one, and which of the numberless and contradicting dogmas are to become the certain basis of education. We all know that each Church thinks itself the only one leading to eternal bliss, and its dogma the only true one. Now whether it is Protestantism or Catholicism, Reformed or Lutheran confession, Anglican or Presbyterian dogma, Roman or Greek doctrine, Mosaic or Islamitic tenets, Buddhaism or Bramahism, or one of the fetish creeds of the Indians or coloured tribes which is to become the lasting and certain 'basis of instruction,' this, no doubt, Virchow will not hesitate to state at the next meeting of the German Association of Naturalists and Physicians."

"At all events, the instruction of the future," according to Virchow, "will be very much simplified. Because the dogma of the Trinity as the basis of mathematics, the dogma of the resurrection of the flesh as the basis of medicine, the dogma of the infallibility as the basis of psychology, the dogma of the Immaculate Conception as the basis of the science of generation, the dogma of the stoppage of the sun as the basis of astronomy, the dogma of the creation of the earth, animals, and plants, as the basis of geology and phylogeny, these or some other dogmas from other creeds, will make all further doctrines rather superfluous. Virchow, this 'critical nature,' of course knows as well as I do, that these dogmas are *not true*, and yet, according to his view, they are not to be replaced as 'bases of instruction' by the theories and hypotheses of modern natural science, of which Virchow says himself that they *may* be true, probably *are* true to a great extent, but have not been 'proved for certain' as yet."

Finally, Haeckel points out that it seems to be bitter irony if Virchow, at the opening address, recalls the memory of Oken, whom he celebrates as the martyr of free science, and at the end of the same address demands that this "liberty of science" shall apply only to *research*, but not to *instruction*, and that no problems, no theories, no hypotheses are to be taught.

In Chapter VI. the application of the theory of descent to socialism is discussed. The author entirely endorses Prof. Oscar's Schmidt's view on the subject, and shows that the theory of descent and the socialistic theory are "like fire and water to one another." The theory of descent is, on the contrary, aristocratic in the highest sense of the word. Of course, from any theory, be it ever so true and sound, the most absurd deductions may be drawn if it is misapplied, and the author warns particularly against the misapplication of scientific theories to political or social questions. Theory and practice rarely correspond in human life. Haeckel points to the history of Christendom to illustrate his argument. "It is certain that the Christian religion, as well as the Buddhistic doctrine, if freed from all dogmatic fables, contain an excellent humane kernel; now it is just this humane and truly social-democratic part of the Christian creed, which proclaims the equality of all men before God, and preaches the 'Love thy neighbour as thyself,' in fact 'love' in its noblest sense, compassion with the poor and unfortunate, &c., —we say these truly humane sides of the Christian faith are so natural, so pure and noble, that we comprise them with pleasure amongst the moral laws of our monistic natural religion. . . . But what, we must ask, have the chosen representatives, the 'God-taught' (Gottgelehrte) priests, made of this 'religion of love'? It is written with letters of blood upon the pages of the history of mankind for the last 1,800 years! All that different Church religions have done for the forcible propagation of their creeds and for annihilation of 'heretics,' all that Jews have done against heathens, Roman Emperors against Christians, Mohammedans against Christians and Jews, all that is surpassed by the hecatombs of human victims which Christianity has slaughtered for the propagation of its doctrine. And indeed Christians against Christians. Rightly-believing Christians against wrongly-believing Christians. We need only think of the middle ages, of the Inquisition, of the unheard-of and inhuman cruelties which the '*most Christian kings*' of Spain and their worthy colleagues in France, Italy, &c., have committed. Hundreds of thousands then died the most cruel death of fire, simply because they did not bend their reason beneath the yoke of the most flagrant superstition, and because their dutiful conviction forbade them to deny what they had recognised to be natural *truths*. There exists no detestable, abominable, or inhuman action which was not then and up to the present day committed in the name of and on account of 'true Christianity.' And what about the *morals of priests*, who designate themselves as servants of God's word, and whose duty first of all should be to regulate their own lives according to the teachings of Christianity? The long, uninterrupted, and horrible chain of crimes of all kinds which forms the history of the Roman pontiffs, gives the best reply to this question. And as these 'representatives of God upon earth' have done, so did their helpmates and subordinates, so did the 'rightly-believing' priests of other confessions, not failing to establish as glaring as possible a contrast between the practices of their own lives and the noble teachings of Christian love which they always talk about. What we have just said of Christianity applies to all other religious and moral doctrines, indeed to all doctrines which in the wide domain of practical philosophy, in the education of the young, and the civilisation of the masses, are to show their power. The theoretical kernel of these doctrines can always and everywhere form the greatest contrast with its practical application, according to the contradictory nature of man. But what does all this matter to the scientific investigator? His sole and only task is to find out *truth*, and to *teach* that what he has *found to be true*, unheeding what consequences may be drawn from his teachings by the various parties in the State or Church."

In the last chapter Haeckel compares the "Ignorabimus" speech of Dubois-Reymond (delivered at the Leipzig meeting in 1872) with Virchow's "Restringamur" address of Munich, and refutes some of the views expressed by Dubois-Reymond, particularly the view that there are two *insurmountable* obstacles in the way of our completely understanding nature and the world, viz., the essence of matter and force and the human consciousness. Haeckel points out that even if the problems in question are not solved at present, no one has a right to declare them unsolvable. He then proceeds to explain the reasons why the opposition to the theory of descent has mainly originated amongst the Berlin biologists, and adduces examples from the history of science to show that a similar opposition to what have now become established truths, has repeatedly sprung from the same quarter. "It seems, indeed, to be the fate of the most interesting of all sciences, of the *history of evolution*, that its most important steps of progress and its greatest discoveries meet with the most powerful and lasting resistance. Just as Wolf's fundamental epigenesis theory, which was founded in 1759, but was acknowledged only in 1812, so Lamarck's theory of descent, founded in 1809, had to wait during full fifty years before Darwin, in 1859, transformed it into the most important acquisition of modern science. And how was this most comprehensive of all biological theories fought against during this time, in spite of all progress of the empirical sciences? Let us only remember how, in 1830, the celebrated George Cuvier silenced the most eloquent advocate of this theory, Geoffroy Saint Hilaire, in the midst of the Paris Academy, and how almost at the same time, in 1829, its founder, the great Lamarck, ended his laborious life, blind and in misery and poverty, while his antagonist, Cuvier, enjoyed the highest honour and the greatest splendour. And yet to-day we know that the despised and derided doctrines of Lamarck and of Geoffroy Saint Hilaire then contained the most important truths, while Cuvier's much-admired and generally-adopted creation doctrine has been now abandoned generally as an absurd and empty error. Now if neither Haller against Wolff, nor Cuvier against Lamarck, could permanently impede the progress of free research, then still less will Virchow succeed in crushing Darwin's admirable theory, even if he be assisted in an unenviable manner by the noisy Capuchin sermons of his friend Bastian. Much as we regret Virchow's hostile position in this great 'combat for truth,' we do not underrate the effect of his well-founded authority upon wider circles. No doubt the hostile attitude

which the greatest part of the Berlin press has assumed with regard to the doctrine of evolution must be attributed to this authority. But much as we must regret the reactionary current in this and other intelligent Berlin circles, yet we must point out that by this evil we are guarded from a far greater one. This greater, indeed the greatest, evil which could befall German science would be a Berlin 'monopoly of knowledge,' the *centralisation of science*. What highly disastrous fruit this centralisation has borne in France, for instance; how the Paris 'monopoly of knowledge' causes a constant degradation of French science, and has led it downwards from the greatest heights for the last half-century, is well known. Probably the wide-spread differentiation and the many-sided individuality of the German national spirit, the often-decried German particularism, will save us from a centralisation of science of this kind, which particularly in our capital, Berlin, would be doubly dangerous. Little as our 'small states' could be politically of any duration or could lead to a useful state-form, they have certainly been most beneficial and fertile for German science. Because this owes its principal advantages over others to the numerous little centres of education, which the capitals of the German small states formed, and to the many little universities which were always in healthy competition with one another. Let us hope that this beneficial decentralisation of science in our politically united Fatherland will continue permanently. Next to the centrifugal striving of our German national spirit, nothing will further this object so much as an energetic resistance to the free progress of science, just as now again it begins to show itself in the capital of the empire. Because at the same rate as this will remain behind in the mighty current of free and unimpeded mental progress, other numerous centres of education in Germany which follow this current enthusiastically, or at least willingly, will outrun it."

"If Emil Dubois Reymond wanted to make his 'Ignorabimus' the watchword of science, and Rudolf Virchow his still further-reaching 'Restringamur,' then from Jena and from a hundred other educational centres they are met with the call—

"*Impavidi progrediamur!*"

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

STUDENTS of Natural Science who would much rather know French and German than Greek will be glad to learn that a very strong memorial against the retention of Greek as a subject for all honour candidates has been presented to Cambridge University. It is signed by ten heads of public schools, including Drs. Hornby (Eton), Butler (Harrow), and Abbott (City of London), Messrs. Matthew Arnold, Carlyle, W. E. Forster, the Bishops of Exeter and Manchester, Dean Cowie, Dean Stanley, and Dr. Vaughan, Prof. Jebb, and Mr. Roby, to say nothing of such bulwarks of science as Mr. Darwin, Prof. Huxley, Sir Joseph Hooker, Mr. Spottiswoode, and Prof. Tyndall.

THE Board of Musical Studies at Cambridge have applied for the appointment of a University Reader in Acoustics.

THE sum in the hands of the Sedgwick Memorial Committee for the erection of a new building for the geological collection is 12,000*l.*, not 1,200*l.* as we stated last week.

King's College (London) *Magazine*, No. 5, vol. ii. of which has been sent us, contains some pleasant reading, but no one would infer from its contents that the College was an important centre of scientific instruction and research.

DR. J. COSSAR EWART has been appointed by the Crown to the Chair of Natural History in the University of Aberdeen.

MR. F. GUTHRIE, formerly of Graaf-Reinet College, has been appointed to the Chair of Mathematics at the South African College, Capetown.

THE *Journal de St. Pétersbourg* gives the following particulars concerning the public provision for education in Russia:—The sum assigned in the Budget of this year for education is 15,971,289 roubles (about 2,395,000*l.*). There are eight Universities (not reckoning that of Helsingfors for Finland), with 5,629 students. Of these 85 are divinity students, 583 belong to the philological faculty, 1,629 to the faculty of law, 30 to that of Eastern languages, 622 to the mathematical faculty, 550 to that of natural science, and 2,130 to the medical faculty. There are 53 ecclesiastical seminaries, with 12,227 pupils; 195 gymnasia and pro-gymnasia, with 50,701 pupils; 56 middle-class schools, with 10,888 scholars. There are 19 military gymnasia, but the number of pupils is not given. For females there are 223 gymnasia and pro-gymnasia, having 34,878 pupils; and this does not include the many institutions which are subject to the control of the Fourth Division of the Imperial Chancellery. There are 68 normal schools and training colleges for teachers, having 4,968 students. There are 10 other such institutions supported by non-public funds. The number of elementary schools in operation this year is 25,491, with 1,074,559 pupils.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 5.—"On the Illumination of Lines of Molecular Pressure, and the Trajectory of Molecules," by William Crookes, F.R.S., V.P.C.S.

Induction Spark through Rarefied Gases. Dark Space round the Negative Pole

The author has examined the dark space which appears round the negative pole of an ordinary vacuum tube when the spark from an induction coil is passed through it. He describes many experiments with different kinds of poles, a varying intensity of spark, and different gases, and arrives at the following propositions:—

Illumination of Lines of Molecular Pressure

a. Setting up an intense molecular vibration in a disk of metal by electrical means excites a molecular disturbance which affects the surface of the disk and the surrounding gas. With a dense gas the disturbance extends a short distance only from the metal; but as rarefaction continues, the layer of molecular disturbance increases in thickness. In air at a pressure of ·078 mm. this molecular disturbance extends for at least 8 mm. from the surface of the disk, forming an oblate spheroid around it.

b. The diameter of this dark space varies with the exhaustion; with the kind of gas in which it is produced; with the temperature of the negative pole; and, in a slight degree, with the intensity of the spark. For equal degrees of exhaustion it is greatest in hydrogen and least in carbonic acid, as compared with air.

c. The shape and size of this dark space do not vary with the distance separating the poles; nor, only very slightly, with alteration of battery power; nor with intensity of spark. When the power is great the brilliancy of the unoccupied parts of the tube overpowers the dark space, rendering it difficult of observation; but, on careful scrutiny, it may still be seen unchanged in size, nor does it alter even when, with a very faint spark, it is scarcely visible. On still further reduction of the power, it fades entirely away, but without change of form.

The author describes numerous experiments, devised to ascertain if this visible layer of molecular disturbance is identical with the invisible layer of molecular pressure or stress, the investigation of which has occupied him for some years.

The Electrical Radiometer

One of these experiments is as follows:—An ordinary radiometer is made, with aluminium disks for vanes, each disk coated with a film of mica. The fly is supported by a hard steel cup instead of a glass cup, and the needle point on which it works is connected by means of a wire with a platinum terminal sealed into the glass. At the top of the radiometer bulb a second terminal is sealed in. The radiometer can therefore be connected with an induction coil, the movable fly being made the negative pole.

Passing over the phenomena observed at low exhaustions, the author finds that, when connected with the coil, a halo of a velvety violet light forms on the metallic side of the vanes, the mica side remaining dark throughout these experiments. As the pressure diminishes a dark space is seen to separate the violet halo from the metal. At a pressure of half a millimetre this dark space extends to the glass, and positive rotation commences.

On continuing the exhaustion the dark space further widens out and appears to flatten itself against the glass, and the rotation becomes very rapid.

When aluminium cups are used for the vanes, instead of disks backed with mica, similar appearances are seen. The velvety violet halo forms over each side of the cup. On increasing the exhaustion the dark space widens out, retaining almost exactly the shape of the cup. The bright margin of the dark space becomes concentrated at the concave side of the cup to a luminous focus, and widens out at the convex side. On further exhaustion the dark space on the convex side touches the glass,

when positive rotation commences, becoming very rapid as the dark space further increases in size, and ultimately flattening against the glass.

Convergence of Molecular Rays to a Focus

The subject next investigated is the convergence of the lines of force to a focus, as observed with the aluminium cup. As this could not be accomplished during rapid rotation an instrument was made having the cup-shaped negative pole fixed, instead of movable. On exhaustion, the convergence of the lines of force to a focus at the concave side was well observed. When the dark space is very much larger than the cup it forms an irregular ellipsoid drawn in towards the focal point. Inside the luminous boundary a focus of dark violet light can be seen converging, and, as the rays diverge on the other side of the focus, spreading beyond the margin of the dark space, the whole appearance being strikingly similar to the rays of the sun reflected from a concave mirror through a foggy atmosphere.

Green Phosphorescent Light of Molecular Impact

At very high exhaustions the dark space becomes so large that it fills the tube. Careful scrutiny still shows the presence of the dark violet focus, and the part of the glass on which fall the rays diverging from this focus shows a sharply defined spot of greenish-yellow light. On still further exhaustion, and especially if the cup is made positive, the whole bulb becomes beautifully illuminated with greenish-yellow phosphorescent light.

This greenish-yellow phosphorescence, characteristic of high exhaustions, is frequently spoken of in the paper. It must be remembered, however, that the particular colour is due to the special kind of soft German glass used. Other kinds of glass phosphoresce in a different colour. The phosphorescence takes place only under the influence of the negative pole. At an exhaustion of 4 M[1] no light other than this is seen in the apparatus. At ·9 M the phosphorescence is about at its maximum. When the exhaustion reaches ·15 M the spark has a difficulty in passing, and the green light appears occasionally in flashes only. At ·06 M the vacuum is almost non-conductive, and a spark can be forced through only by increasing the intensity of the coil, and well insulating the tube and wires leading to it. Beyond that exhaustion nothing has been observed.

Focus of Molecular Force

In an apparatus specially constructed for observing the position of the focus, the author found that the focal point of the green phosphorescent light was at the centre of curvature, showing that the molecules by which it is produced are projected in a direction normal to the surface of the pole. Before reaching the best exhaustion for the green light, another focus of blue-violet light is observed; this varies in position, getting further from the pole as the exhaustion increases. In the apparatus described, at an exhaustion of 19·3 M, these two foci are seen simultaneously, the green being at the centre of curvature, while the blue focus is at nearly twice the distance.

Nature of the Green Phosphorescent Light

The author adduces the following characteristics of the green phosphorescent light as distinguishing it from the ordinary light observed in vacuum-tubes at lower exhaustions:—

a. The green focus cannot be seen in the space of the tube, but where the projected beam strikes the glass only.

b. The position of the positive pole in the tube makes scarcely any difference to the direction and intensity of the lines of force which produce the green light. The positive pole may be placed in the tube either at the extremity opposite the negative pole, or below it, or by its side.

c. The spectrum of the green light is a continuous one, most of the red and the higher blue rays being absent; while the spectrum of the light observed in the tube at lower exhaustions is characteristic of the residual gas. No difference can be detected by spectrum examination in the green light, whether the residual gas be nitrogen, hydrogen, or carbonic acid.

d. The green phosphorescence commences at a different exhaustion in different gases.

e. The viscosity of a gas is almost as persistent a characteristic of its individuality as its spectrum. The author refers to a preliminary note and a diagram[2] of the variation of viscosity of air, hydrogen, and other gases at exhaustions between 240 M and ·1 M. From these and other unpublished results, the author finds that the viscosity of a gas undergoes very little diminution between atmospheric pressure and an exhaustion at which the green phosphorescence can be detected. When, however, the spectral and other characteristics of the gas begin to disappear, the viscosity also commences to decline, and at an exhaustion at which the green phosphorescence is most brilliant the viscosity has rapidly sunk to an insignificant amount.

f. The rays exciting green phosphorescence will not turn a corner in the slightest degree, but radiate from the negative pole in straight lines, casting strong and sharply-defined shadows from objects which happen to be in their path. On the other hand, the ordinary luminescence of vacuum tubes will travel hither and thither along any number of curves and angles.

Projection of Molecular Shadows

The author next examines the phenomena of shadows cast by the green light. The best and sharpest shadows are cast by flat disks and not by narrow pointed poles; no green light whatever is seen in the shadow itself, no matter how thin or whatever may be the substance from which it is thrown.

From these and other experiments, fully described in the paper, he ventures to advance the theory that the induction-spark actually illuminates the lines of molecular pressure caused by the electrical excitement of the negative pole. The thickness of the dark space is the measure of the mean length of the path between successive collisions of the molecules. The extra velocity with which the molecules rebound from the excited negative pole keep back the more slowly-moving molecules which are advancing towards that pole. The conflict occurs at the boundary of the dark space, where the luminous margin bears witness to the energy of the collisions.

When the exhaustion is sufficiently high for the mean length of path between successive collisions to be greater than the distance between the fly and the glass, the swiftly-moving, rebounding molecules spend their force, in part or in whole, on the sides of the vessel, and the production of light is the consequence of this sudden arrest of velocity. The light actually proceeds from the glass, and is caused by fluorescence or phosphorescence on its surface. No light is produced by a mica or quartz screen, and the more fluorescent the material the better the luminosity. Here the consideration arises that the greenish yellow light is an effect of the direct impact of the molecules, in the same electrical state, on the surface of the glass. The shadows are not optical, but are molecular shadows, revealed only by an ordinary illuminating effect; this is proved by the sharpness of the shadow when projected from a wide pole.

Phosphorescence of Thin Films

An experiment is next described in which a film of uranium glass, sufficiently thin to show colours of thin plates, is placed in front of a thick plate of the same glass, the whole being inclosed in a tube with terminals, and exhausted to a few millionths of an atmosphere. Of this the following observations are recorded:—

a. The uranium film, being next to the negative pole, casts a strong shadow on the plate.

b. On making contact with the coil, the thin film flashes out suddenly all over its surface with a yellowish phosphorescence, which, however, instantly disappears. The uncovered part of the plate does not become phosphorescent quite suddenly, but the phosphorescence is permanent as long as the coil is kept at work.

c. With an exceedingly faint spark the film remains more luminous than the plate, but on intensifying the spark the luminosity of the film sinks and that of the uncovered part of the plate increases.

d. If a single intense spark be suddenly sent through the tube, the film becomes very luminous, while the plate remains dark.

These experiments are conclusive against the phosphorescence being an effect of the radiation of phosphorogenic ultra-violet light from a thin layer of arrested molecules at the surface of the glass, for were this the case, the film could under no circumstances be superior to the plate.

The momentary phosphorescence and rapid fading of the film prove more than this. The molecular bombardment is too much for the thin film. It responds thereto at first, but immediately gets heated by the impacts, and then ceases to be luminous.

[1] M signifies the millionth of an atmosphere.
[2] *Proc.* Roy. Soc., Nov. 16, 1876, vol. xxv. p. 305.

The plate, however, being thick, bears the hammering without growing hot enough to lose its power of phosphorescing.

Mechanical Action of Projected Molecules

When the coil was first turned on, the thin film was driven back at the moment of becoming phosphorescent, showing that an actual material blow had been given by the molecules. Experiments are next described in which this mechanical action is rendered more evident. A small rotating fly, capable of being moved about in any part of an exhausted bulb, is used as an indicator, and by appropriate means the molecular shadow of an aluminium plate is projected along the bulb. Whether entirely in, or entirely out of the shadow, the indicator scarcely moves, but when immersed so that one-half is exposed to molecular impact, the fly rotates with extreme velocity.

Magnetic Deflection of Lines of Molecular Force

With this apparatus another phenomenon was investigated. It is found that the stream of molecules, whose impact on the glass occasions evolution of light, is very sensitive to magnetic influence, and by bringing one pole of an electro-magnet—or even of a small permanent magnet—near, the shadow can be twisted to the right or to the left.

When the little indicator was placed entirely within the molecular shadow, no movement was produced. As soon, however, as an adjacent electro-magnet was excited, the shadow was twisted half off the indicator, which immediately rotated with great speed.

The Trajectory of Molecules

The amount of deflection of the stream of molecules forming a shadow is in proportion to the magnetic power employed.

The trajectory of the molecules forming the shadow is curved; when under magnetic influence the action of the magnet is to twist the trajectory of the molecules round in a direction at an angle to their free path, and to a greater extent, as they are nearer the magnet: the direction of twist being that of the electric current passing round the electro-magnet.

Laws of Magnetic Deflection

An apparatus was constructed so that the deflection of a spot of light was used instead of that of a shadow, a horse-shoe magnet being placed underneath the negative pole to deflect the trajectory. The action of the north pole being to give the line of molecules a spiral twist one way, and that of the south pole being to twist it the other way, the two poles side by side compel the line to move in a straight line up or down along a plane at right angles to the plane of the magnet and a line joining its poles.

The ray of molecules does not appear to obey Ampère's law, as it would were it a perfectly flexible conductor, joining the negative and the positive pole. The molecules are projected from the negative, but the position of the positive pole, whether in front, at the side, or even behind the negative pole, has no influence on their subsequent behaviour, either in producing phosphorescence, or mechanical effects, or in their magnetic deflection. The magnet gives their line of path a spiral twist greater or less according to its power, but diminishing as the molecules get further off.

Numerous experiments were tried in this apparatus with different gases, and with the magnet in and out of position.

Working with exhausted air it was found that the spot of green phosphorescence on the screen is visible at an exhaustion of 102·6 M, when the mean free path of the molecules, measured by the thickness of the dark space round the negative pole, is only 12 mm. Hence, it follows that a number of molecules sufficient to excite green phosphorescence on the screen are projected the whole distance from the pole to the screen, or 102 mm., without being stopped by collisions.

Alteration of Molecular Velocity

If we suppose the magnet to be permanently in position, and thus to exert a uniform downward pull on the molecules, we perceive that their trajectory is much curved at low exhaustions, and gets flatter as the exhaustion increases. A flatter trajectory corresponds to a higher velocity. This may arise from one of two conditions; either the initial impulse given by the negative pole is stronger, or the resisting medium is rarer. The latter is probably the true one. The molecules which produce the green phosphorescence must be looked upon as in a state differing from those arrested by frequent collisions. The latter impede the velocity of the free molecules and allow longer time for magnetism to act on them; for, although the deflecting force of magnetism might be expected to increase with the velocity of the molecules, Prof. Stokes has pointed out that it would have to increase as the square of the velocity, in order that the deflection should be as great at high as at low velocities.

Comparing the free molecules to cannon-balls, the magnetic pull to the earth's gravitation, and the electrical excitation of the negative pole to the explosion of the powder in the gun, the trajectory will be flat when no gravitation acts, and curved when under the influence of gravitation. It is also much curved when the ball passes through a dense resisting medium, it is less curved when the resisting medium gets rarer; and, as already shown, intensifying the induction spark, equivalent to increasing the charge of powder, gives greater initial velocity, and, therefore, flattens the trajectory. The parallelism is still closer if we compare the evolution of light seen when the shot strikes the target, with the phosphorescence on the glass screen from molecular impacts.

Focus of Heat of Molecular Impact

The author finally describes an apparatus in which he shows that great heat is evolved when the concentrated focus of rays from a nearly hemispherical aluminium cup is deflected sideways to the walls of the glass tube by a magnet. By using a somewhat larger hemisphere and allowing the negative focus to fall on a strip of platinum foil, the heat rises to the melting point of platinum.

An Ultra-gaseous State of Matter

The paper concludes with some theoretical speculations on the state in which the matter exists in these highly exhausted vessels. The modern idea of the gaseous state is based upon the supposition that a given space contains millions of millions of molecules in rapid movement in all directions, each having millions of encounters in a second. In such a case the length of the mean free path of the molecules is exceedingly small as compared with the dimensions of the vessel, and the properties which constitute the ordinary gaseous state of matter, which depend upon constant collisions, are observed. But by great rarefaction the free path is made so long that the hits in a given time may be disregarded in comparison to the misses, in which case the average molecule is allowed to obey its own motions or laws without interference; and if the mean free path is comparable to the dimensions of the vessel, the properties which constitute gaseity are reduced to a minimum, and the matter becomes exalted to an ultra-gaseous state, in which the very decided but hitherto masked properties now under investigation come into play.

Rays of Molecular Light

In speaking of a ray of molecular light, the author has been guided more by a desire for conciseness of expression than by a wish to advance a novel theory. But he believes that the comparison, under these special circumstances, is strictly correct, and that he is as well entitled to speak of a ray of molecular or emissive light when its presence is detected only by the light evolved when it falls on a suitable screen, as he is to speak of a sunbeam in a darkened room as a ray of vibratory or ordinary light when its presence is to be seen only by interposing an opaque body in its path. In each case the invisible line of force is spoken of as a ray of light, and if custom has sanctioned this as applied to the undulatory theory, it cannot be wrong to apply the expression to emissive light. The term emissive light must, however, be restricted to the rays between the negative pole and the luminous screen: the light by which the eye then sees the screen is, of course, undulatory.

The phenomena in these exhausted tubes reveal to physical science a new world—a world where matter exists in a fourth state, where the corpuscular theory of light holds good, and where light does not always move in a straight line; but where we can never enter, and in which we must be content to observe and experiment from the outside.

Chemical Society, December 5.—Dr. Gladstone, president, in the chair.—Prof. Tidy read a lengthy and important paper on the processes for determining the organic purity of potable waters. The conclusions at which the author arrives, after many experiments and a careful examination of the comparative analyses of over 1,600 waters, may be briefly summed up as follows: *The ammonia process* furnishes results which are marked by singular inconstancy, and are not delicate enough to allow the recognition

and classification of the finer grades of purity or impurity. The errors incidental to the process form an array of difficulties which become infinitely serious, seeing that the range (as regards albumenoid ammonia) between pure and dirty waters is comparatively small. *The combustion process* has all the evils of evaporation to encounter, but the organic carbon estimation is trustworthy; the organic nitrogen determination, however, scarcely yields absolutely trustworthy evidence on which to found an opinion as to the probable source of the organic matter. The process, nevertheless, is of great value. *The oxygen* (permanganate) *process* avoids the errors incidental to evaporation; its results (when properly used) are constant and extremely delicate; it draws a sharp line between the putrescent or probably pernicious and the non-putrescent or probably harmless organic matter; by it a bad water can never be passed as good. As far as the three processes are concerned, the oxygen and combustion processes give closely concordant results, whilst those yielded by the ammonia process are often at direct variance with both.

Photographic Society, November 12.—James Glashier, F.R.S., in the chair.—After the medals awarded for the best pictures in the exhibition had taken place, a paper by Leon Warnerke was read—photographic notes from a travel in Russia with exhibition of various works, apparatus, and materials. John Thomson, F.R.G.S., described his photographic experiences in Cyprus. Mr. Warnerke described the artistic and scientific progress of photography in Russia as having arrived at a high state of perfection, as also the very important position which photo-lithography occupies in the Government establishments of the country where large maps of the Russian frontiers are produced.

BOSTON, U.S.A.

American Academy of Arts and Sciences, November 13.—Hon. Charles Francis Adams in the chair.—Prof. Mitchell, of the U.S. Coast Survey, read a monograph upon the tides of the Gulf of Maine. The results of the late surveys prove that a lift of the tide far out from shore requires an almost inappreciable time to be felt along the coast. The variations in the tides were shown to come from the north rather than from the south. In the discussion of Prof. Mitchell's paper Prof. Benjamin Peirce maintained that the results corroborated his own theory of vibrations and nodal points.—Prof. A. E. Dolbear, of Tuft's College, read a paper upon his claims of the invention of the speaking-telephone, and exhibited his early models and also a great variety of new speaking-telephones. Among these were a Morse sounder transformed into a telephone; a miniature voltaic cell, one plate of which was spoken against, and speech thus transmitted; an electrophone depending upon the variable resistance of the extra spark, which can transmit speech over a distance of more than two hundred miles; various forms of transmitters and modifications of Reiz's telephone, which Prof. Dolbear said are innumerable.—Mr. N. D. C. Hodges exhibited a new instrument for determining the magnetic dip. Two soft iron bars joined at right angles move on a vertical graduated circle. A small magnet with a mirror is suspended at the point of crossing of the pieces of soft iron. When the latter make equal angles with the line of dip, the magnet remains at zero. By four simple reversals and measurements the residual magnetism of the iron is eliminated. The instrument gives very constant results and requires less time to make an observation than the ordinary dipping needle.

PARIS

Academy of Sciences, December 2.—M. Fizeau in the chair.—The following papers were read:—On the torsion of prisms of mixtilinear base, and on a peculiarity which may be presented by certain uses of the logarithmic co-ordinate of the isothermal cylindrical system of Lamé, by M. De Saint Venant.—M. Marey was elected Member for the section of Medicine and Surgery in the room of the late M. Cl. Bernard, the other candidates being MM. Bert, Charcot, and Gubler.—Experimental researches on meteoritic nickelised irons; mode of formation of concretionated syssidera, by M. Meunier. The mixture of chlorides of iron and nickel gives, by reduction in hydrogen, alloys perfectly definite, and sometimes beautifully crystallised. Association of the alloys together can be effected in two ways (specified). Next, grains of peridot or fragments of dunite can easily be covered with a continuous coat of various alloys of iron and nickel, the metallic concretion sometimes penetrating into the fine fissures of the stone. By placing the pieces of rock repeatedly in the incrusting medium fed with diverse mixtures of the two chlorides, superposed deposits of various alloys are obtained, and a complete facsimile of the cosmic rocks in question.—On a new phenomenon of static electricity, by M. Govi. A reference to his former experiments on the phenomenon studied by M. Duter. Different liquids having given different amounts of contraction, and mercury no contraction, he inferred condensation of the liquid against the walls of the jar. He apparently doubts M. Duter's conclusion.—On the electromotive force of induction arising from rotation of the sun; determination of its amount and direction, whatever the distance of the induced body, by M. Quet. He gives a mathematical estimate of the force, with formulæ.—Note on the effects of vapours of sulphide of carbon, by M. Poincaré. He experimented on animals, with reference to the symptoms presented by workmen in vulcanisation of caoutchouc. Guinea pigs and frogs resist the action much less than man; and the period of excitation is wanting in them, the manifestations being mainly paralytic. The auricles are distended with dark blood, livid spots appear in the lungs, the brain is often reduced to a diffluent pulp, and drops apparently of sulphide of carbon form in the cerebral vessels, blocking the passage of blood corpuscles and sometimes causing rupture. The author considers the use of vulcanised caoutchouc should be restricted to really useful objects, and that the manufacture of small balloons and toys of it should be interdicted.—On the mode of formation of some phylloxeric nodosities, by M. d'Arbaumont.—Latitude of Algiers, and fundamental azimuth of the Algerian triangulation, by M. Perrier. The author describes his method.—Nebulæ discovered and observed at the Observatory of Marseilles, by M. Stephan.—Double stars; certain groups of perspective, by M. Flammarion.—Evaluation of a definite integral, by M. Appell.—On the repulsion resulting from radiation, by Mr. Crookes.—Note on cholalic acid, by M. Destrem.—Researches on vaso-motor nerves, by MM. Dastre and Morat. The principal branch of termination of the sciatic nerve plays, with regard to the region of the finger, the *rôle* of a vaso-constrictor nerve, and there is no ground for supposing, in this nerve-trunk, vaso-dilator nerves either more or less than in the cervical cord of the sympathetic. Thus the controverted point as to whether the sciatic is a vaso-dilator nerve, is answered in the negative. The authors generalise the results, applying them to the nervous trunks which go to the skin.—On the cardiac and respiratory effects of irritations of certain sensitive nerves of the heart, and on the cardiac effects produced by irritation of sensitive nerves of the respiratory apparatus, by M. François-Franck. Different effects are produced according as an irritating injection (say hydrate of chloral) is made into the right or the left heart; in the former case there is diastolic stoppage of the heart, in the latter systolic. (The mechanism of these effects is studied.)—On the change of form of fixed cells of loose connective tissue in artificial œdema, by M. Renaut.

PARADOXICAL PHILOSOPHY

Paradoxical Philosophy. A Sequel to the "Unseen Universe." (London: Macmillan and Co., 1878.)

ON opening this book, the general appearance of the pages, and some of the phrases on which we happened to light made us somewhat doubtful whether it lay within our jurisdiction, as it is not the practice of NATURE to review either novels or theological works.

In the dedication, however, the book is described as an account of the *Proceedings* of a learned society, a species of literature which we are under a special vow to rescue from oblivion, even when, as in this case, the proceedings are those of one of those jubilee meetings, in which learned men seem to aim rather at being lively than scientific.

On the title-page itself there is no name to indicate whether the author is one of those who by previous conviction have rendered themselves liable to our surveillance, but on the opposite page we find "The Unseen Universe; or, Physical Speculations on a Future State," to which this book is a "Sequel," ascribed to the well-known names of Balfour Stewart and P. G. Tait.

Mr. Browning has expressed his regret that the one volume in which Rafaelle wrote his sonnets, and the one angel which Dante was drawing when he was interrupted by "people of importance," are lost to the world. We shall therefore make the most of our opportunity when two eminent men of science, "driven," as they tell us, "by the exigencies of the subject," have laid down all the instruments of their art, shaken the very chalk from their hands, and, locking up their laboratories, have betaken themselves to those blissful country seats where Philonous long ago convinced Hylas that there can be no heat in the fire and no matter in the world; and where in more recent times, Peacock and Mallock have brought together in larger groups the more picturesque of contemporary opinions.

In this book we do not indeed catch those echoes of well-known voices in which the citizens of the "New Republic" tell us how they prefer to regard themselves as thinking, taking care, all the while, that no actual thought shall disturb their enjoyment of the luxury of extravagant opinion. The members of the Paradoxical Society, with their guest, Dr. Hermann Stoffkraft, are far too earnest to adopt this pose of mind, but they exhibit that sympathy in fundamentals overlaid with variety in opinions which is one of the main conditions of good-fellowship. Dr. Stoffkraft, in spite of his name and of his office as the single-handed opponent of the thesis of the book, makes it his chief care so to brandish his materialistic weapons as not to hurt the feelings of his friends; and when, near the end of the book, he gets a little out of temper, it is about matters with which a materialist, as such, has no concern.

As the book is not a novel there is no literary reason for not telling "what became of the Doctor," as narrated in the last chapter. He goes to Strathkelpie Castle to take part in an investigation of spiritualistic phenomena. He begins by detecting the mode in which one young lady performs her spirit-rapping, but forthwith falls into an "electro-biological" courtship of another, and, this proving successful, he is persuaded by his wife and her priest to renounce the black arts in the lump as works of the foul fiend; and then we are told that, having quieted his spirit by a few evolutions in four dimensions, he has now settled down to compose his "Exposition of the Relations between Religion and Science," which he intends to be a thoroughly matured production.

The Doctor—and, indeed, most of the other characters—are no mere materialised spirits, or opinions labelled with names of the *Euphranor* and *Alciphron* type. They do not reduce their subject to a *caput mortuum* by an exhaustive treatment, but take care, like well-bred people, to drop it and pass on to another before we have time to suspect that the last word has been said.

We cannot accuse the authors of leading us through the mazy paths of science only to entrap us into some peculiar form of theological belief. On the contrary, they avail themselves of the general interest in theological dogmas to imbue their readers at unawares with the newest doctrines of science. There must be many who would never have heard of Carnot's reversible engine, if they had not been led through its cycle of operations while endeavouring to explore the Unseen Universe. No book containing so much thoroughly scientific matter would have passed through seven editions in so short a time without the allurement of some more human interest.

Nor need we fear to draw down on NATURE the admonition which fell on the inner ear of the poet—

> "Thou pratest here where thou art least;
> This faith hath many a purer priest,
> And many an abler voice than thou."

For even those words and phrases which seemed at first sight to remove the book from the field of our criticism, are found on a nearer view to have acquired a new, and indeed a *paradoxical* sense, for which no right of sanctuary can be claimed.

The words on the title-page: "In te, Domine, speravi, non confundar in æternum," may recall to an ordinary reader the aspiration of the Hebrew Psalmist, the closing prayer of the "Te Deum," or the dying words of Francis Xavier; and men of science, as such, are not to be supposed incapable either of the nobler hopes or of the nobler fears to which their fellow-men have attained. Here, however, we find these venerable words employed to express a conviction of the perpetual validity of the "Principle of Continuity," enforced by the tremendous sanction, that if at any place or at any time a single exception to that principle were to occur, a general collapse of every intellect in the universe would be the inevitable result.

There are other well-known words in which St. Paul contrasts things seen with things unseen. These also are put in a prominent place by the authors of the "Unseen Universe." What, then, is the Unseen to which they raise their thoughts?

In the first place the luminiferous æther, the tremors of which are the dynamical equivalent of all the energy which has been lost by radiation from the various systems of grosser matter which it surrounds. In the second place a still more subtle medium, imagined by Sir William Thomson as possibly capable of furnishing an explana-

tion of the properties of sensible bodies; on the hypothesis that they are built up of ring vortices set in motion by some supernatural power in a frictionless liquid: beyond which we are to suppose an indefinite succession of media, not hitherto imagined by any one, each manifoldly more subtle than any of those preceding it. To exercise the mind in speculations on such media may be a most delightful employment for those who are intellectually fitted to indulge in it, though we cannot see why they should on that account appropriate the words of St. Paul.

NATURE is a journal of science, and one of the severest tests of a scientific mind is to discern the limits of the legitimate application of scientific methods. We shall therefore endeavour to keep within the bounds of science in speaking of the subject-matter of this book, remembering that there are many things in heaven and earth which, by the selection required for the application of our scientific methods, have been excluded from our philosophy.

No new discoveries can make the argument against the personal existence of man after death any stronger than it has appeared to be ever since men began to die, and no language can express it more forcibly than the words of the Psalmist:—

"His breath goeth forth, he returneth to his earth; in that very day his thoughts perish."

Physiology may supply a continually increasing number of illustrations of the dependence of our actions, mental as well as bodily, on the condition of our material organs, but none of these can render any more certain those facts about death which our earliest ancestors knew as well as our latest posterity can ever learn them.

Science has, indeed, made some progress in clearing away the haze of materialism which clung so long to men's notions about the soul, in spite of their dogmatic statements about its immateriality. No anatomist now looks forward to being able to demonstrate my soul by dissecting it out of my pineal gland, or to determine the quantity of it by the process of double weighing. The notion that the soul exerts force lingered longer. We find it even in the late Isaac Taylor's "Physical Theory of a Future State." It was admitted that one body might set another in motion; but it was asserted that in every case, if we only trace the chain of phenomena far enough back, we must come to a body set in motion by the direct action of a soul.

It would be rash to assert that any experiments on living beings have as yet been conducted with such precision as to account for every foot-pound of work done by an animal in terms of the diminution of the intrinsic energy of the body and its contents; but the principle of the conservation of energy has acquired so much scientific weight during the last twenty years that no physiologist would feel any confidence in an experiment which showed a considerable difference between the work done by an animal and the balance of the account of energy received and spent.

Science has thus compelled us to admit that that which distinguishes a living body from a dead one is neither a material thing, nor that more refined entity, a "form of energy." There are methods, however, by which the application of energy may be directed without interfering with its amount. Is the soul like the engine-driver, who does not draw the train himself, but, by means of certain valves, directs the course of the steam so as to drive the engine forward or backward, or to stop it?

The dynamical theory of a conservative material system shows us, however, that *in general* the present configuration and motion determines the whole course of the system, exceptions to this rule occurring only at the instants when the system passes through certain isolated and singular phases, at which a strictly infinitesimal force may determine the course of the system to any one of a finite number of equally possible paths, as the pointsman at a railway junction directs the train to one set of rails or another. Prof. B. Stewart has expounded a theory of this kind in his book on "The Conservation of Energy," and MM. de St. Venant and Boussinesq have examined the corresponding phase of some purely mathematical problems.

The science which rejoices in the name of "Psychophysik" has made considerable progress in the study of the phenomena which accompany our sensations and voluntary motions. We are taught that many of the processes which we suppose entirely under the control of our own will are subject to the strictest laws of succession, with which we have no power of interfering; and we are shown how to verify the conclusions of the science by deducing from it methods of physical and mental training for ourselves and others.

Thus science strips off, one after the other, the more or less gross materialisations by which we endeavour to form an objective image of the soul, till men of science, speculating, in their non-scientific intervals, like other men on what science may possibly lead to, have prophesied that we shall soon have to confess that the soul is nothing else than a function of certain complex material systems.

Men of science, however, are but men, and therefore occasionally contemplate their souls from within. Those who, like Du Bois-Reymond, cannot admit that sensation or consciousness can be a function of a material system, are led to the conception of a double mind.

"On the one side the acting, inventing, unconscious material mind, which puts the muscles into motion, and determines the world's history; this is nothing else but the mechanics of atoms, and is subject to the causal law, and on the other side the inactive, contemplative, remembering, fancying, conscious, immaterial mind, which feels pleasure and pain, love, and hate; this one lies outside of the mechanics of matter, and cares nothing for cause and effect."

We might ask Prof. Du Bois-Reymond which of these it is that does right or wrong, and knows that it is his act, and that he is responsible for it, but we must go on to the other view of the case, which Dr. Stoffkraft alludes to at p. 78, although by some law of the *Paradoxical*, he is not allowed to pursue a subject which might have afforded excellent sport to the Society.

"I feel myself compelled to believe," says the learned Doctor, "that all kinds of matter have their motions accompanied with certain simple sensations. In a word, all matter is, in some occult sense, alive."

This is what we may call the "levelling up" policy, and it has been expounded with great clearness by Prof.

von Nägeli in a lecture, of which a translation was given in NATURE, vol. xvi. p. 531.

He can draw no line across the chain of being, and say that sensation and consciousness do not extend below that line. He cannot doubt that every molecule possesses something related, though distantly, to sensation, "since each one feels the presence, the particular condition, the peculiar forces of the other, and, accordingly, has the inclination to move, and under circumstances really begins to move—becomes alive as it were;" . . . "If, therefore, the molecules feel something which is related to sensation, then this must be pleasure if they can respond to attraction and repulsion, *i.e.*, follow their inclination or disinclination; it must be displeasure if they are forced to execute some opposite movement, and it must be neither pleasure nor displeasure if they remain at rest."

Prof. von Nägeli must have forgotten his dynamics, or he would have remembered that the molecules, like the planets, move along like blessed gods. They cannot be disturbed from the path of their choice by the action of any forces, for they have a constant and perpetual will to render to every force precisely that amount of deflexion which is due to it. Their condition must, therefore, be one of unmixed and unbroken pleasure.

But even if a man were built up of thinking atoms would the thoughts of the man have any relation to the thoughts of the atoms? Those who try to account for mental processes by the combined action of atoms do so, not by the thoughts of the atoms, but by their motions.

Dr. Stoffkraft explains the origin of consciousness at p. 77 and at p. 107. We recommend to his attention Mr. Herbert Spencer's statement in his "Principles of Psychology," § 179, where he shows in a most triumphant manner how, under certain circumstances, "there must arise a consciousness." Such statements, carefully studied, may contribute to the further progress of science in the path which we have been describing, by showing more clearly that consciousness cannot be the result of a plexus of nervous communications any more than of a congeries of plastidule souls.

Personality is often spoken of as if it were another name for the continuity of consciousness as reproduced in memory, but it is impossible to deal with personality as if it were something objective that we could reason about. My knowledge that I am is quite independent of my recollection that I was, and also of my belief that, for a certain number of years, I have never ceased to be. But as soon as we plunge into the abysmal depths of personality we get beyond the limits of science, for all science, and, indeed, every form of human speech, is about objects capable of being known by the speaker and the hearer. Whenever we pretend to talk about the Subject we are really dealing with an Object under a false name, for the first proposition about the Subject, namely, "I am," cannot be used in the same sense by any two of us, and therefore can never become part of science at all.

The progress of science, therefore, so far as we have been able to follow it, has added nothing of importance to what has always been known about the physical consequences of death, but has rather tended to deepen the distinction between the visible part, which perishes before our eyes, and that which we are ourselves, and to show that this personality, with respect to its nature as well as to its destiny, lies quite beyond the range of science.

J. CLERK MAXWELL

SCIENCE CLASS-BOOKS

The London Science Class-Books. Edited by G. Carey Foster, F.R.S., and Philip Magnus, B.Sc. *Biological Series.* 1. *Botany—Outlines of Morphology and Physiology.* 2. *Botany—Outlines of Classification of Plants.* By W. Ramsay McNab, M.D. 3. *Zoology of the Vertebrate Animals.* 4. *Zoology of the Invertebrate Animals.* By Prof. A. Macalister. (London: Longmans, Green and Co., 1878.)

THE editors of this series of Elementary Science Class-Books intend that the works shall all be composed with special reference to school teaching; that they shall be suited to the capabilities and comprehension of boys and girls during their school course, while they shall at the same time afford trustworthy and accurate information presented in such a way that it may serve as a basis for more advanced study. In thus announcing their scheme the editors would seem to indicate that they have learned to appreciate the very great want that exists in all our public schools of just such a series of class-books as they undertake to supply; and though the standard at which they aim cannot be regarded as a high one, still most judges will agree that it is both a suitable and a proper one, and it is one that we wish the editors every success in their carrying of it out. If the natural sciences are to be taught in our schools the scholars must have class-books of these sciences, and we take it as a good sign that the demand for such class-books is in this new series being supplied. The information in the present series is to be accurate and trustworthy, and the names of the authors of the four books already published of the biological series is a sufficient guarantee that this is so. The information is to be suited to the capabilities of girls and boys during their school-days, and still it is to be presented in such a way as to form the basis of a higher study. The authors' names, however distinguished, will be no necessary guarantee of this. It is not given to every one to be able to write an elementary book that may serve as the basis for a more advanced study. In the first two class-books on our list the author indeed does not even make the attempt. In his preface Prof. McNab declares that it has been thought advisable to make his class-books on Botany such as would serve as a basis for the teaching in the higher classes of schools, and such as would supply the wants of medical students and others wishing to acquire a knowledge of the subject. We think this a pity, for we certainly at once miss that strictly elementary treatment of the subject, that full statement and discussion of the fundamental facts thereof, which we were led to expect, not by the author, but by his editors; and however useful and instructive these two class-books may be, the aim that we fancy they should have kept in view is lost in the endeavour, to quote their authors' own words, that they should "serve as an introduction to the celebrated text-book of the distinguished German botanist, whose "Lehr-

buch der Botanik" has been lately translated by Professors Bennett and Thiselton Dyer, and which has been published in the Clarendon Press Series. After the class-book is mastered the manual is to be studied."

The first class-book treats of the morphology and physiology of plants. In it three chapters are devoted to the morphology, and five chapters to the physiology. Like the little text-book of Thomé, it presents to the student's view a cell of a fungal plant, as an instance of the simplest conception of a vegetable cell; but while such a structure is a cell, surely it is neither the most simple, nor certainly is it the most perfect form of a cell to be the first given to a beginner. The structure of the cell-wall and its growth are well treated of, but we do not like to find the word "absorption" used in the account of the formation of wood vessels, bordered pits, &c.; this word is very likely to mislead the student, especially when he finds it used in another chapter to denote the imbibition of moisture. So far as we know, the cellulose cell-wall is in no case decomposed molecule by molecule, and these are not taken up as they are laid down; and yet would it not require that all this should be done ere the term internal absorption could be correctly applied?

The subjects of the formation of new cells, and of the substances contained in protoplasm, are thoroughly well done; a few technical words here and there occurring, and not explained, will demand the attention of the teacher. It would have been well had the chemical formulæ for starch, and some of the other members of the cellulose group, be given, in addition to the formula for cellulose. Such formulæ would have enabled the student the better to understand the change of one organic compound, such as starch, into another, such as sugar. In passing we may observe that Sach's "Text-Book" is very defective also in this respect; indeed, the word sugar is not to be found in its index, and nowhere in the text is its composition given. Chapter II. treats of the tissues. Perhaps a few more technical words are here used than are absolutely necessary, but no doubt a great deal of exactness is attained by their use. The details are compressed into the smallest compass, but are quite up to the very newest facts; and because each word in such a chapter stands to express a good deal, we venture to take exception to the employment of the word development in the following sentence:—"Permanent tissue is formed by the further development of those cells of the meristem which have lost the power of dividing," and which have assumed some permanent form. It is just in such cells that no true development can take place. In Chapter III. the external conformation of plants is briefly treated of. In Chapter IV. we find The Nutrition of Plants. "As the chemical elements out of which the plant constructs its organic substance," the author enumerates "carbon, hydrogen, oxygen, nitrogen, and sulphur;" might he not have added iron? True, it may still be doubted whether iron forms an integral constituent of the chemical formula of chlorophyll, but without it the plant, as a plant, cannot "construct its organic substance." The processes of assimilation and metastasis are very conveniently tabulated, and the student carefully going over this chapter will, we should think, be able to understand it without any help from a teacher. It is a chapter which does the author great credit, and almost comes up to the standard of the editors. Only one comment we venture to make on it. Taking it for granted that Nägeli has somewhere said that the *ultimate* solid particles of plants are more or less crystalline, a conception beyond our powers, how then can the mode of their growth be very different from that occurring in minerals, crystals, &c.? The Fifth Chapter is concerned with the relation of the general conditions of the life of plants. The Sixth treats of the growth of plants. The author limits the term growth to an increase in bulk, accompanied by a deposit of some new constructive material. He thus considerably limits the term, as we believe correctly defined by Herbert Spencer. The subject of the tension found in growing parts is treated at a length out of due proportion to the treatment of the other subjects in the volume, and in such a class-book we think it would have sufficed to have given the results of Sachs' experiments on the periodicity of growth, and not to have copied his tabular statements in such detail. The last chapters are devoted to the subjects of the reproduction of plants and their classification.

The second class-book, also by Prof. McNab, is a continuation of the first, but is devoted to the special morphology and outlines of a classification of plants. The classification of the flowerless plants is based on that of Sachs, though this is here and there altered. We think the author acts rather prematurely in placing such families as those of the Chytridiaceæ and Chlorochytridiaceæ yet as among the Oosporeæ. The Lichens are regarded as ascomycetous fungi parasitic on algæ; this we think right. Cohn's very convenient names Bryophyta and Pteridophyta are adopted for the groups of the mosses and the Vascular Cryptogams; and as an instance that very recent facts in the life history of the Cryptogams has not escaped the attention of the author, we perceive that he mentions that the branches of the Horse-tails arise in an axillary manner, and not as believed up to Janczewski's researches, in an endogenous manner. So much space is devoted to the Cryptogams that the treatment of the flowering plants is greatly curtailed. These two little volumes have been well and painstakingly compiled; they may be safely placed in the hands of a student who knows some little of the subject about which they treat, and they cannot fail to be very useful to every teacher of the natural sciences in our upper schools.

The two little volumes on "Zoology," by Prof. Macalister, are of quite another type. They aim at presenting, in as simple a form as possible, the leading characters of vertebrate and invertebrate animals. In these, special care has been taken to dispense with all unnecessary technicalities, and when such, owing to the nature of the case, arise, they are carefully explained. We would have wished something more novel than most of the woodcut illustrations, though we acknowledge that among the invertebrates some of the illustrations are modern; but we feel glad to find each volume with a carefully drawn up index, the loss of which will doubtless be felt by many a student of Prof. McNab's two class-books; while they will be found to afford trustworthy and accurate information. This will be found given in a way quite suited to the comprehension of our average minded girls and boys.

OUR BOOK SHELF

Studies from the Physiological Laboratory in the University of Cambridge. Edited by the Trinity Prælector in Physiology. Part III. (Cambridge: Printed at the University Press, 1877.)

THIS volume of 165 pages, together with numerous elaborate plates—the largest of the Cambridge Biological "Studies" yet published—is a most pleasing indication of a vigorous spirit of research in a body which has by many been thought to be solely educational. It is not, indeed, the number of the memoirs and papers here collected, but their quality, which makes them worthy of the university whose name they bear on the title-page. In quantity they are far from commensurate with the latent means and opportunities of the colleges and University of Cambridge, but in their thoroughness and dignity they display a spirit which would do honour to any university. They represent a new feature in the history of biological science in this country, viz., the recognised official charge of biological research in high places, where it has been too long neglected. The Biological and Physiological School of Cambridge is a rare and valuable "sport" in the offspring of an organism of decided conservative tendencies: may we not hope that, ere long, Oxford will give birth to a similar healthy monster?

All the papers of this volume have been published before in the *Journal of Anatomy and Physiology*, or elsewhere; but we are not the less glad, on that account, to see the present collection. If the cause of scientific research were more secure in England than it is, the publication of special collections of memoirs of the various schools might be held to be an unnecessary luxury, or even—since rivalry may become ungenerous—a positively dangerous habit. Under our present conditions, however, it is not only pleasant to be reminded now and again of the various centres of organised research among us, but it materially strengthens the hands of English scientific workers to invest the different growing schools with somewhat of a personal and individual interest.

The volume contains physiological and anatomical papers, chiefly in zoology, but also in botany. Dr. Michael Foster and Mr. Dew-Smith contribute a most interesting paper on the effects of the constant current on the heart, which is a continuation of the work they did on the reaction of the snail's heart to electrical currents. Mr. J. N. Langley has a paper on the action of pilocarpin on the submaxillary gland of the dog. Mr. Gaskell reprints one of his papers on the vaso-motor nerves of striated muscles. Mr. F. M. Balfour contributes an important section of his now published monograph on the development of elasmobranch fishes, viz., the development of their spinal nerves; as well as a paper on the spinal nerves of amphioxus. Mr. Marshall follows with a paper on the development of the nerves in birds. Mr. Bullar has a paper, with plates, on the generative organs of parasitic isopoda; Mr. Bridge one on the cranial osteology of *Amia calva*, also admirably illustrated; and Mr. Sidney Vines a short communication on the digestive ferment of nepenthes.

The American Quarterly Microscopical Journal, containing the Transactions of the New York Microscopical Society. Edited by Romyn Hitchcock. Vol. I., No. 1. October. (New York: Hitchcock and Hall, 1878.)

COMMENCING, as this new journal does, on the lines of our own *Quarterly Journal of Microscopical Science*, and somewhat under the like auspices, we trust it may have the same worthy career, and be equally well thought of. The first number is beautifully printed on excellent paper, and contains some eighty-two pages belonging to the journal proper, while the *Transactions* of the New York Microscopical Society extend to some sixteen pages more. The six plates, on their part, are good, but not up to the same standard of execution as the letterpress, and fall a good deal below those that generally appear in our own microscopical journal. The chief contents of this part are—1. On the Sting of the Honey Bee, by J. D. Hyatt. Plates I. and II. 2. Description of some New Species of Diatoms, by H. L. Smith. Plate III. 3. Observations on several Forms of Saprolegniaceæ, by F. B. Hine. Plates IV. to VI. Only the first part of this paper is given, and the list of works referred to by the author is given at the end of the paper, so perhaps it may be premature to suggest that English writers on this subject are not altogether wanting, as he would seem to think; but has he not Dr. Lindstedt's Synopsis, and does not this refer to such? 4. The Oil Immersion Lenses of Zeiss compared with the Objectives of Spencer and Sons, by H. L. Smith. 5. On the Microscopical Examination of Fibers (fibres?), by W. H. Seaman. 6. Emigration in Passive Hyperæmia, by W. T. Belfield. 7. On a New Device for Dark-field Illumination, by W. Leighton. Among the shorter articles we may mention one reprinted, with full acknowledgment, on the Spore Formation in the Mesocarpeæ, from our own columns, and an account of the National Microscopical Congress held last August at Indianapolis, Indiana.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Locusts and Sun-Spots

As the locust (*Œdipoda migratoria*, or *Acridium perigrinum?*) is a frequent and occasionally aggravating accompaniment of drought and famine, it cannot but be interesting to notice that periodical incursions of this insect into the temperate zone are apparently regulated in some way by the terrestrial meteorological abnormalities which accompany the varying phases of the sun-spots.

Dr. F. G. Hahn, in his treatise "Ueber die Beziehungen der Sonnenfleckenperiode zu meteorologischen Erscheinungen," atfer remarking that locusts will probably only visit the temperate regions in great numbers during unusually hot and dry years (on account of the brood), and abandon them again in wet and cold years, shows, from a list furnished by Dr. W. Köppen, of Hamburg, embracing the period 1800-1862, that in Europe they begin coming about the epoch of minimum sun-spot, paying annual visits from thence up to the epoch of maximum sun-spot, after which they disappear altogether until the next following epoch of sun-spot minimum.

In the following table I give Dr. Hahn's dates for their visitations in Europe, with some additional ones on the authority of M. Camille Flammarion, and Mr. Walford of the Statistical Society, which include other regions of the north temperate zone. I also give the corresponding sun-spot epochs in each case, according to Wolf. The capital letters in parentheses attached to the dates, indicate the authorities respectively alluded to above.

LOCUSTS.	SUN-SPOTS.	
Date of Visitation in Temperate Zone.	Min.	Max.
1613 (F)	1610·8	1615·0
1690 (F)	1689·5	1693·0
1748[1]–1749 (F)	1745 0	1750·3
1800 annually up to 1806 (H)	1798·3	1804·2
1811 ,, ,, 1816 (H)	1810·6	1816·4
1820 ,, ,, 1829 (H)	1823·3	1829·9
1832 (F) 1834 (F) 1837 annually up to 1839 (H)	1833·9	1837·2
1844 annually up to 1848 (H)	1843·5	1848·1
1855 ,, ,, 1862 (H)	1856·0	1860·1
1866 (F) 1868 (W)	1867·2	1870·6
1874 annually up to 1878 (W)	1877(?)	—

[1] See *Gentleman's Magazine* for July, 1748, pp. 331 and 414.

The remarkable fact displayed in his portion of the above table, that locusts only make their appearance in great numbers in the interval from minimum to maximum sun-spot and never during the interval from maximum to minimum sun-spot, is evidently regarded by Dr. Hahn as affording some additional collateral proof in favour of the relation he had already partially established between the rainfalls of Central Europe and the sun-spots, viz., that the interval from minimum to maximum sun-spot is in general drier and warmer than that from maximum to minimum sun-spot. The added dates apparently exhibit a relation to the sun-spot epochs similar to those given by Dr. Hahn.

Whether the laws which regulate the visitations of locusts are the same in other parts of the world or not, it is at all events suggestive to notice that the dates of their general appearance throughout the world, given by Mr. Walford in a recent paper to the Statistical Society, entitled, "Famines of the World, Past and Present," exhibit the same relation to the sun-spots as that noted by Dr. Hahn in the case of their visits to Europe.

The date of apparition, the locality visited, and the epoch of sun-spot minimum corresponding, are given below.

Date of Apparition.	Locality visited.	Epoch of Minimum Sun-Spot.
1802	India	1798·3
1812–13	,,	1810·6
1833–35	,,	1833·9
1855	United States	1856·0
1868	,,	1867·2
1874–77	,,	1877(?)
1878	China, Spain, Algeria, Bosnia, India	1877(?)

In the face of such an apparent predilection on the part of locusts to swarm during the minimum epoch of sun-spots, it might, I think, be advantageous to institute an extensive comparison of all past visitations of these insects with the eleven-year cycle of sun-spots. This after due allowance had been made for any known natural cycles of incubation, might possibly bring to light a physical cycle of visitation, the size and position of the area affected by which would, perhaps, afford some indication of the corresponding limits of the rainfall variation.

The Range of the Mammoth

THE criticism by Mr. Clement Reid of my paper recently read before the Geological Society, and not yet published, renders it necessary to remind him that his views as to the mammoth not being pre-glacial are not new, but were advanced by me ten years ago (*Pop. Science Review*, 1868, p. 275; *Geol. Mag.*, v. 7, July, 1868), and afterwards given up by the light of a wider experience. His arrangement of the complicated glacial deposits of Britain in one linear series, like all similar attempts, appears to me to be based on the fallacy that a difference in the character of the strata, in different areas, implies a difference in point of time. His divisions seem to me purely local, and mostly peculiar to the eastern counties. I see no reason for believing that, while five out of the six proposed were being accumulated east of the Pennine chain, there were no glacial phenomena in the west, in Lancashire or Cheshire, until the last phase, or the sixth of the eastern divisions; or, in other words, that the lower boulder clay of Lancashire and Cheshire is the equivalent of the last division. On the contrary, the marine sands and gravels covering the lower boulder clays, on both sides of the Pennine chain, and occupying a large area round Crewe, Stafford, and in the Trent Valley, is to me a well-marked horizon, defining the upper from the lower series of boulder clays. It is very likely that the lower boulder clay of Lancashire and Cheshire is the equivalent of the lower boulder clay series of Norfolk and Suffolk, as well as of the "moraine profonde" of Scotland. It must, however, be admitted that the correlation of the glacial deposits in various parts of Britain has not yet been satisfactorily made out. "Tot homines quot sententiæ."

To group them, as they are frequently now grouped, in one linear series, seems to me almost as useless as to construct a history of Europe in which the dynasties ruling various kingdoms at the same time are described one after another, and taken to belong to different periods because they were different dynasties.

W. BOYD DAWKINS

Fossil Floras of the Arctic Regions

THE author of the valuable paper communicated in NATURE, vol xix. p. 124, on "The Fossil Floras of the Arctic Regions," will find in an essay of mine, entitled "Thalassa," and published in the course of last year, a number of facts and arguments in corroboration of his views regarding the influence of oceanic currents upon climate. In this essay, which is mainly founded upon the observations made on board H.M.S. *Challenger*, I have endeavoured to show how a relatively trifling elevation or depression of the sea-coast or of the bed of the ocean may considerably alter the configuration of an oceanic basin; how such an alteration must affect the direction, volume and temperature of existing currents, and thus have a tendency to change the climate and ultimately the distribution of animal and plant life in the regions bordering on the oceanic basin. I also (p. 29–30) ventured to express the opinion that "it appears hardly necessary to go in search of vast cosmic changes, such as an alteration in the position of the terrestrial axis, a diminution in the amount of solar heat . . . . while we have, close at hand, an agency whose effect upon climatic conditions may be said to be a matter of daily experience, and which is sufficiently powerful to establish, in almost any region on the earth's surface, the small difference of temperature which is a decree of life or of death to numerous animal and vegetable organisms." To this I may now add, that the influence of oceanic currents upon climate and upon the distribution of life will be most felt and produce the most remarkable results in the *Arctic* and *sub-Arctic* regions, which, as we know, may at one period be swept by powerful polar currents, at another invaded by vast masses of warm water brought there by currents from the tropical regions, such, for example, as the Gulf Stream.

The facts brought to light by recent sounding-operations regarding the configuration of the sea-bottom and the distribution of oceanic depths has led me to the conclusion that our continents and oceanic basins, such as they appear at the present day, are of immense antiquity; that changes in the distribution of land and water require for their accomplishment long periods, which, for all we know, may alternate with periods of repose or even of retrocession; and that, consequently, the influence of these changes upon currents and upon climate must be equally slow and uncertain in its duration. If, therefore, the effect of oceanic currents upon climate appears as an important factor, which can no longer be neglected in any discussion on the flora and fauna of past geological epochs, on the other hand, the slow and uncertain progress of the changes above mentioned seems to afford ample scope for the operation of other causes which, besides climate and temperature, determine the existence of certain species in a given area of the earth's surface.

J. J. WILD

The Microphone

TWO subjects of interest in connection with the practical application of the microphone have lately been brought to my notice by Raja Sir T. Madava Row, K.C.S.I., Dewan of Baroda. In the hope of securing a little assistance from some of your scientific readers I hasten to lay them before you.

The first question is with reference to the use of a microphone as a stethoscope. It seems that native ladies of high position decline altogether to allow a doctor to examine the chest in the ordinary manner. Sooner than submit to such an examination they would prefer to die—certainly rather a staggering fact for those imbued with European ideas. In the cause of humanity it is therefore desirable to do something for those whose position and caste would be imperilled by *direct* examination. If the microphone could be so delicately arranged as to transmit the auscultatory sounds, a medical ear, even at a distance, would surely be able to detect the existence of any disease of the heart or lungs. In the few experiments that we have made with our limited appliances we have been able to hear the ticking of a watch at a distance of about 200 yards, and the roar of a black ant when attacked by his companion, but as yet we have heard no internal sounds from the human breast. Perhaps with better devised instruments some one may have been able to obtain that which has yet been denied to us. I am sure many native ladies would be glad to get an affirmative answer to the question, "Can the microphone be used as a stethoscope?"

The second subject seems to me to be a much more difficult one to grapple with. Sir Madava Row writes to me as follows:—

"In the undulating region of Travancore, where the water-bearing strata heave and fall according to the locality concerned, I have come across a set of professional men who are generally consulted by those who wish to sink wells in view to ascertain whether, at a given spot, a well may be sunk with the probability of finding water *near enough*. These professional men undertake to predict where the springs will be found near, and where they will be found at great depth, and their predictions are generally verified with great accuracy. I took some trouble to ascertain how these men are enabled to predict the proximity, or otherwise, of the springs underground. Brushing aside the ceremonies and incantations they perform in view to deceive others and perhaps themselves also, I found that they detect the proximity of the subterranean springs by lying down on the bare ground in the dead silence of night, with the ear in contact with the ground, and trying to *hear the sound* of the flow of water in the strata beneath. By practice the ear is made very sensitive, and the degree of distinctness with which they hear the sound of flowing water enables them approximately to predict the depth of the springs. It is in this manner that appropriate spots are selected for sinking wells.

"Now, would any of the instruments you are experimenting with magnify the sound of the subterranean flow of water so as to greatly facilitate the process I have described? If so, it may be a considerable practical gain."

To this query I have hitherto been able to return no other answer than a negative one. Both the subjects are practical ones, and I only hope that there will be before long some light cast upon them. THOS. S. TAIT

Baroda, India, November 4

Leaf-Sheaths and the Growth of Plants

THE latest results of M. Bert's researches into the growth of plants (see *Comptes Rendus*, vol. 87, p. 695, November 4), have led me to publish an observation which I made on the inner sheaths of young leaves this last spring. The spring before last I was struck with the crimson-like colour of these silky sheaths on many trees, whereas the young leaves they cover are of a tender green, and it naturally occurred to me that their purpose was not only to form a wrapper to the leaf, but also a coloured screen, which would allow the red rays of the spectrum to pass, and to a certain extent quench the blue rays. But I could not understand why the latter rays should be cut off, since they are highly actinic, and the leaves themselves are green. Last spring I carefully noted the tints of the leaf-sheaths of different trees, with the following results:—

Name of Tree.	Tint of Inner Leaf Sheath.	Tint of Outer Leaf Sheath.
Elm	Red (crimson)	Reddish-brown.
Lime	Red (crimson)	Reddish-brown.
Beech	Red (crimson)	Brown.
Sycamore	Red (crimson).	
Ash		Sooty-black.
Horse-chestnut	Red (crimson).	
Maple	Bright-red.	
Birch	Brown.	
Oak	Brownish-red.	
The Bramble	Reddish.	
The Hawthorn	Red.	
Certain Roses	Red.	
Wild Cherry	Red.	

Sometimes the bark on the stem of young sycamore shoots and the top leaflets were tinged with a deep reddish-brown. The overlapping tips of young leaves in buds were frequently reddish, and the majority of outer leaf-cases were a warm or reddish-brown. The shining buds of the horse-chestnut afforded a fine example of the phenomenon. The leaf-cases were of a strong red, like carmine, the exposed tip of each sheath leaflet being dyed a deeper red at the middle, shading off to the edges, where they overlapped. Under this protective curtain was a layer of flossy fibre, like cotton, swathing the pale young leaves underneath.

The recent researches of M. Bert throw light on this interesting subject. He finds that plants kept under green glass shades soon perish, because these intercept the red or less refrangible rays of the spectrum, and allow the blue or more refrangible rays to pass. Red glass, on the contrary, sustains life, although it becomes enfeebled by reason of the withdrawal of all the blue rays. M. Bert thinks that all the rays are necessary to the full vigour of the plant, and in the proportion of the solar spectrum; but it would appear from the care which nature has taken to redden the young leaf-cases, that for certain trees at least, the spring sunlight is richer in blue rays than she wishes, and therefore she has arranged that part of them shall be excluded, while all the red rays (or those which affect the maximum reduction of carbonic acid gas, and the building up of tissues) are allowed to pass into the leaf. I should add that this effect of colour is evidently superadded to the other functions of the sheath, as it usually appears as a more or less perfect colouring of the *outer surface* of the sheath only. JOHN MUNRO

West Croydon

Hornets

THE following fact, which I have been enabled to verify concerning a hornet, may be interesting to some of the readers of NATURE:—In a letter I received from my grandson, a very observing and accurate young naturalist, there was the following statement, dated October 13, 1878, Tunbridge Wells:—

"Last week I caught a splendid large hornet on the hall window, and last Saturday I caught a smaller one on a small oak-tree in Hurst Wood (Tunbridge Wells). He was engaged in eating some sticky, whitish stuff which had come out of the tree in several places where it had been cut or bruised. This stuff seemed to attract all the insects in the neighbourhood, especially swarms of flies. There were two red admirals (butterflies), two hornets, four wasps, and hundreds of bluebottles and other small flies, busily engaged in eating this substance, which was bored with small round holes. On Sunday, as we came home from Speldhurst Church, we passed the same tree, and on it, to my great surprise, I caught half a hornet, which was very active, running about the tree, and seemed to be quite happy and comfortable. He had no abdomen at all, except a small piece of the upper skin, which hung on; his left wings were very much battered, and he had lost his left hind leg." This half hornet was brought home and examined, keeping actively alive until the evening, when it was destroyed for the sake of preservation. I had an opportunity of examining the half hornet alluded to very soon after, and the facts detailed in the letter I have quoted were ascertained to be quite correct. This hornet was a small specimen, and I found all the abdomen gone except a small portion of the upper part of the first joint, which still remained attached to the thorax. The left wings were much broken, and one hind leg gone. In this disabled state, how long the hornet might have lived is a point which I regret was not ascertained.

Raystead, Worthing WM. WILSON SAUNDERS

Equine Sagacity

A PLEASANT story has just come to us from the Cape of Good Hope. In Graaf-Reinett, as in all the old Dutch towns in the colony, there is, in the centre of the place, a large market square, where the farmers, traders, and others, arriving with their produce at any hour of the day or night, may "out-span" the oxen or horses from their waggons, send the cattle out to the "commonage" to feed, while they bivouac at their waggons, as is the wont of African travellers to do, until the eight o'clock morning market auction.

An old horse belonging to one of these parties had wandered about in search of grass and water—vainly, no doubt, for it was during the severe drought from which the country is but now recovering. Coming to the great bare market-place, and finding a knot of men talking there, he singled out one of them, and pulled him by the sleeve with his teeth. The man, thinking the horse might possibly bite, repulsed him, but as it was not very roughly done, he returned to the charge, with the same reception; but he was a persevering animal, and practically demonstrated the axiom that "perseverance gains the day," for upon his taking the chosen sleeve for the third time between his teeth, the owner awoke to the idea that a deed of kindness might be required of him; so, putting his hand upon the horse's neck, he said, "All right, old fellow; march on!" The horse at once led the way to a pump at the further side of the square. Some coloured servants were lounging about the spot. One of them, at the bidding of the white man, filled a bucket with water; three times was the bucket replenished and emptied before the "great thirst" was assuaged, and then the grateful brute almost spoke his thanks to his white friend by rubbing his

nose gently against his arm, after which he walked off with a great sigh of relief.

A story somewhat analogous to the foregoing was told me by a friend, whose uncle, an old country squire in one of our western counties, had a favourite hunter in a loose box in the stable. One warm summer day he was "athirst," and could get no water. He tried to draw the groom's attention to the fact, but without success. The horse was not to be discouraged; he evidently gave the matter consideration. The thirst was pressing. All at once he remembered that he always had a certain halter put upon his head when led to the water. He knew where it hung. He managed to unhook it from its peg, and *carried it to the groom!* who at once, in great admiration of the knowledgable brute, rewarded him in the manner he desired. M. CAREY-HOBSON

Colour-Blindness

DR. PRIOR'S letter is almost entirely philological, and therefore does not come within my province. I have alluded to the colour-blind impression of white in my paper in the *Phil. Trans.*

I should like to know more about the eyesight of the person who says he cannot distinguish snow.

The latter part of the first paragraph of my letter on p. 120 should run, "In pigments, neutral green appears to me gray."

Magnetic Storm, May 14, 1878

REFERRING to a letter from the Rev. S. J. Perry in NATURE, vol. xviii. p. 617, reporting the magnetic disturbances observed at Stonyhurst, Melbourne, and Shanghai, on May 14, it may interest your readers to learn that earth-current disturbances were also noted on the Persian Gulf cables from 4 P.M. (Kurrachee time) on the 15th up to 5 A.M. on the following day.

Unusually strong earth-currents were also observed on June 3 and 4, on the cables between Bushire and Kurrachee; the current-strength at 2.40 P.M. on the 3rd, and 12.20 A.M. on the 4th, being reported as equal to fourteen Daniell's cells.

Kurrachee, November 8 HENRY C. MANCE

"Measuring the Height of Clouds"

THE electric light promising to be of great intensity at a small cost, the thought occurred to me that it might be used with advantage for the purpose of ascertaining the height of clouds. For, supposing an electric lamp sending a beam of light to the clouds, the spot where the light meets the latter, will be more or less visible, and we are obviously able to determine trigonometrically the height of the cloud.

By using two lamps, or a lamp and two reflectors, we may easily find also the rate at which clouds travel, by bringing the plane, passing through the axes of the beams of light, parallel to the direction in which the clouds move, and by noting the time it takes a cloud to travel from one beam of light to the other, having, of course, determined also the actual distance between the two spots of light on the clouds.

The above refers to observations during the night only, but by making use of coloured light, or by bringing a substance in the carbons of the lamp, the spectrum of which is easily recognisable, we might probably be able to work also during day-time.

Kew J. F. WILKE

The Weather

AFTER a week of unusually cold weather, the mean temperature having been 28°·5, and the wind constant from a northerly point, a thaw set in yesterday, and the wind became westerly, when immediately after sunset a rather unusual condition of weather occurred: viz., the rapid formation of a complete sheet of ice on the roads, though at the time, and till eleven P.M., the thermometer was 2° or 3° above the freezing-point.

As the sky was overcast at the time radiation cannot well account for it. Owing to the penetration of the cold, the surface must have retained a temperature considerably below 32° for some time after the air had become warmer and damper, so that the moisture was at once congealed.

Clifton, December 16 G. S. THOMSON

THE LAST EXPERIMENTS WITH THE 80-TON GUN

THE last experiments with the 80-ton gun at Woolwich deserve to be recorded, if only for the sake of showing that our scientific artillerists appear to be working in the proper channel. The last shot fired from the monster piece of ordnance was with the unprecedented charge of 460 lbs. of powder, and yet there was not so much strain upon the gun as that formerly exerted by charges one hundred lbs. less. The reason of this is in the main due to a change having been made in the character of the gunpowder employed; for whenever the former powder was used, even in lesser quantity, the pressure of the gas inside the gun rose at once. This would not so much matter if it could be shown that with the increase of strain, the work of the shot increased also. But such is not the case. For instance, in the case of two shots fired last week, one was sent on its way by 460 lbs. of prismatic powder, recording a velocity, we are told, of 1,626 per second, and a strain inside the gun of 19½ tons, while the other, with but 425 lbs. of cube powder, had a speed of only 1,600 feet, while it exerted a strain upon the weapon of 21 tons per square inch. The gun has been chambered—or in other words the cartridge cavity enlarged—to permit the introduction of heavier charges, as also to allow of a certain amount of air-space in the cartridge; but this modification in the weapon, beneficial as it may be, does not account, as we have shown, for the decrease upon the strain of the gun. This is due to the change in the powder.

In most of the former experiments a gunpowder of solid cubes, irregular in shape and measuring about an inch and a half, were employed; the recent results have been secured by thick six-sided prisms, about an inch across, and so accurately shaped that they may be packed together very closely. There is a single perforation in the middle of this prismatic powder, which, by the way, is of German origin, and when the cartridge has been securely packed so as to represent one solid mass, the perforations running through the whole length of the charge permit of the same being rapidly kindled. If the perforations were not there, half the charge would probably be expelled the gun before it was kindled; so that a packed cartridge of prismatic powder represents as nearly as possible a solid charge with tubes running its entire length, through which the kindling flames pass.

It has, of late, grown to be an axiom that the larger the gun the larger must be the grains of powder. A large grain of gunpowder burns slow because the fire is some time reaching the centre, and a slow-burning powder is what artillerists require for rifled guns. In a smoothbore weapon the cannon ball fits loosely, and may be expelled at a bound; but in rifled cannon the shot, so to speak, moves upon a sort of railway, and it would never do to get the shot into motion too suddenly. An undue strain would be exerted upon the gun, while the velocity of the shot would not be increased. For a rifled gun, therefore, a slow-burning charge is absolutely necessary, and this is to be secured only by reducing the surface to be kindled. In the case of the prismatic powder, the grains, if they may be called by that name, are so closely packed that no fire can get between them, and hence the action of kindling is still further reduced.

Not only is the shape and density of powder grains now attracting particular attention, but the percentage of moisture contained in the material has also lately been under study. The amount of water in gunpowder to the minute extent existing in ordinary samples is found to influence combustion in a very marked degree, and nothing but an exhaustive series of trials can give sufficient data for practical application of so important an element in the science of explosives. In the meantime chemists are pointing out yet another source of uncertainty in the combustion of gunpowder, to which, notwithstanding

their repeated warnings, but little attention has hitherto been given. We mean the composition of the charcoal. According to the manner of preparing this, the method adopted for charring and the material employed, so does the chemical composition of the charcoal differ. Some samples, for instance, prove on analysis to contain 85 per cent. of carbon, while others have 20 per cent. less; it is scarcely to be expected that gunpowder made from the two kinds will have the same burning qualities, and yet with gunpowder manufactures charcoal is charcoal, no matter how much its component parts of carbon, hydrogen, oxygen, and ash may differ. It is of little use, therefore, paying any particular attention to the physical qualities of gunpowder so long as its chemical composition is almost entirely ignored.

The manner in which the strain upon the gun and the velocity of the shot are measured at Woolwich are worthy of explanation. The means employed are of the simplest kind. The maximum pressure of the gases inside the gun as the shot is being expelled is recorded by what is termed a "crusher gauge." This is no more than a tiny pillar of copper. The pillar is placed loosely in a tube, the end of which, made of steel, stands firm and fast no matter what the pressure. So that the soft copper pillar, when subjected to the action of the gas, gets compressed, or crushed, and assumes something of a barrel shape. The pillar and its case, being affixed to the base of the shot, gets the full pressure of the gunpowder gases, and its length afterwards denotes how much this pressure has been. To secure more trustworthy pillars of the metal it is the practice to compress them first of all to a certain degree, to remove any honeycomb or imperfection, and, thus uniformly compressed, they may be relied upon to record the strain with accuracy. Comparison of the fired pillar, with other pillars which have been subjected to known pressures, at once reveals the degree of force to which the former has been subjected in the gun. The maximum pressure, or strain, to which the 80-ton gun should be subjected, is set down as 25 tons on the square inch, and it is with the aid of this "crusher-gauge" that the strain exerted in the various experiments has been ascertained.

The initial velocity of a shot, or, in other words, the rapidity with which a projectile flies at the outset of its career, is now measured by an electrical instrument, the invention of Major le Boulengé, a Belgian officer. As in the case of other instruments of a like nature, the shot is made to break through two wire screens, placed at some distance from one another. The interval is usually about 100 feet. The screen is simply a wooden framework with fine wires zigzagging across, and it is these fine wires which the shot cuts. One screen is near the muzzle of the gun, and the other at the distance we have mentioned. No. 1 screen is in connection with an electro-magnet in the instrument-house, and No. 2 screen with a second, the two magnets hanging close together. While the wires in front of the screen are perfect, an electric current passes without interruption, and the electro-magnets in connection with them are endowed with power, but this power ceases as soon as the shot cuts the wires of the screen. Before the gun is fired there is suspended to the magnets two rods of iron, which remain, however, only so long as the magnets are magnets. When the shot is fired, No. 1 screen is torn, and down falls the rod suspended to No. 1 magnet; an instant afterwards, when the shot has reached No. 2 screen, No. 2 magnet also loses it virtue, and down falls the second rod. The time between the falling of the two rods is so small, that ere the first has fallen half its length the second has dropped upon a trigger, which trigger darts out and strikes the side of No. 1 rod. When the latter is picked up, the first thing is to examine the surface for the mark of the trigger, for the position of this mark, whether high or low, tells the operator what he wants to know. The rod being of a given weight, always takes the same time to fall, and according whether it has fallen half or quarter its length, so the time taken by the shot to travel between the screens has been long or short. In a word, the rod has only to be compared with a prepared scale in order to read off the number of feet per second at which the shot has gone on its way.

THE REGISTRARSHIP OF LONDON UNIVERSITY

LAST week we referred to Dr. Carpenter's intended resignation of the Registrarship of the University of London. We have before us his letter intimating his desire to resign his post on May 31 next, and the resolution of the Senate in connection therewith. By the date mentioned Dr. Carpenter will have completed his twenty-third year as Registrar, and, including his previous nine years as Examiner, his connection with the University has extended over four-fifths of its term of existence, and over a corresponding proportion of his own professional life. There is no doubt that the success of this great institution is to a great extent owing to the energy and faithfulness with which Dr. Carpenter has discharged the duties of his post. It has been fortunate for the University as well as for science that a man of so eminent a scientific position has been so long and so intimately connected with it, and it will be extremely difficult to find one capable of taking up adequately Dr. Carpenter's work. We have pleasure in publishing the resolution of the Senate, to which we have referred.

"In accepting the Registrar's resignation of the important office he has held since 1856, the Senate desire to record their sense not only of the ability, judgment, and fidelity with which he has uniformly discharged its duties, but also of the zeal and efficiency with which he has on all occasions exerted himself both within and beyond the limits of his official obligation, for the promotion of the best interests of the University.

"The Senate would further record their conviction that it has been of special advantage to the University, during the twenty years of its most rapid development, to have had the services of a Registrar who, besides being an excellent administrator of its affairs, has attained, by his scientific labours, a position which has given him a just weight and influence over those with whom he has been brought officially into contact.

"The Senate strongly recommend the Registrar to the favourable consideration of the Lords of Her Majesty's Treasury as having acquired, by 'special services,' a claim to a larger superannuation allowance than that to which he is entitled by mere length of service."

ABOUT FISHES' HEADS

IN a former number (vol. xvii., p. 286), in a note "About Fishes' Tails," we called attention to some recent observations of Alexander Agassiz on the young stages of some fishes, in which he showed the wonderful changes that, as development went on, took place in their caudal fins; yet strange though these changes are, they seem as nothing to those that take place in some fishes' heads, and the facts first noticed by Steenstrup, and the theory which, by a marvellous power of intuition, he built up thereon, as to the eye in a flounder passing from the right side of its head to its left, have been in a great measure confirmed, and perhaps in a greater measure added to, by the painstaking observations quite recently published, of Alexander Agassiz,[1] from which it would now seem very certain that even the most shapeless adult fishes begin their life as quite symmetrical young creatures. No more

[1] *Proceedings* of the American Academy of Arts and Sciences, vol. xiv., July, 1878.

unsymmetrical fish can probably be found than an adult flounder with its unsymmetrical tail, with its twisted head, with its two goggly eyes—brought together on the one side of that head—and yet examine a flounder while yet young. "The one I captured," writes Agassiz, "was so transparent as to rival the most watery of jelly fishes. When placed on a flat glass dish it could only be distinguished by allowing the light to strike it in certain directions, otherwise all that was visible were the two apparently disembodied bright emerald eyes moving more or less actively. It was over an inch in length, the position of the eyes was perfectly symmetrical, and they were placed at a considerable distance from the anterior extremity of the snout; the dorsal fin extended almost to the nostrils." From this beautiful symmetry how then did the strange want of it in the adult fish arise? Long ago (1863) this question presented itself to Steenstrup. He had a small number of very young flounders preserved in alcohol, and from an examination of these he answered the query thus:—The young flounder, after a short time, takes to lying on its right side, why no one can tell, but with this result that the eye of that side begins to turn inwards, and passing through the tissues of the head, transfers itself to the left side. So strange seemed this explanation, that Malm's observations, in which he seemed to show that this apparent transference was really due to a torsion or twisting of the entire head, appeared to some to be, perhaps, the most probable explanation of the extraordinary phenomenon described by Steenstrup, and yet in Steenstrup's paper he very clearly showed that any ordinary torsion of the head of a flounder on its axis was wholly insufficient to explain the final position of its eyes. Since 1863 a good deal has been written upon the subject of the want of symmetry in the heads of the so-called flat fishes, more especially by Sir Wyville Thomson, Dr. Ramsay Traquair, Dr. Schiodte, Dr. Klein, Professors Reichert and Canestrini; but the most important and the latest memoir is the one just published by A. Agassiz, which forms a second part of his memoir, "On the Young Stages of Osseous Fishes," and is devoted chiefly to the development of the flounders. This memoir is accompanied by eight excellent plates, some of which show very well the changes of form through which some of the young flounders pass. The young flounders of some species attain a considerable size ere they show the least tendency to favour one side more than another, and before there is any change in the position of the eyes. They then swim vertically, at least when they come up to the surface to feed. This they will do on bright sunny days, about ten o'clock in the morning, while the water is very smooth, and they will then be seen to devour greedily swarms of embryo crustaceans of all orders. Some will after a while settle down on their left sides, which then in time become colourless and blind, these would be called dextral, while in some just the reverse takes place; but no matter on which side they take to resting on, the exchange is the same. First there is a slight advance of the eye of the blind side towards the snout, then this rises higher and higher towards the medial line of the head; it now becomes more and more visible from the coloured side, until at last it quite passes over. This transfer commences, in eight species observed by Agassiz, very early in life, while all the face-bones of the skull are quite cartilaginous, and, by a combined process of rotation and translation, it is completed long before these have become ossified. So far these observations of A. Agassiz were completely in conformity with the observations of Malm, who, it will be remembered, did not trace the changes undergone during the process; and they seemed to be completely antagonistic to the idea of Steenstrup, that the eye from the blind side passed through the tissues of the head and came out on the coloured side. But in the late summer of 1875 a little shoal of some fifteen quite transparent flounders were captured by Agassiz, on a quiet and brilliant morning, on the surface of the water at the mouth of the harbour of Newport. They were swimming vertically, and violently rushing after the minute entomostraca which swarmed on the surface. They were at once transferred to shallow glass jars, in which they would remain at the bottom on their right sides, for hours immovable. When disturbed they were rapid in their movements, frequently jumping out of the water. When swimming vertically they usually moved obliquely, the tail being carried lower than the head. When one of these was looked at in profile, its right eye could be seen through the head, slightly in advance and a little above the left eye; owing to the great transparency of the body, the right eye was then nearly as useful as if placed on the left side. Gradually it rose, until in about six days it was well above the left eye; shortly after, wonderful to relate, it was seen to sink into the tissues at the base of the dorsal fin between this and the frontal; slowly it sank until the huge orbit became reduced to a mere circular opening. Little by little this became smaller and smaller, the eye pushed its way deeper into the tissues, until an additional opening was formed on the left side. At this stage there were three orbital openings, though of course but two eyes. The original or right-orbital opening soon became closed and the coloured side had its two eyes. Thus was the suggestion of Steenstrup proved to be correct by careful observation on a living form, and what is of even greater interest, A. Agassiz is, from having thus, as it were, seen all round the subject, enabled to suggest that the difference between these two methods of the transference of these eyes is not so great as would at first appear, the eye that sinks through the tissues, only taking a slightly shorter cut to arrive at its destination than the one that travels round the frontal bone. He is also able to hint at facts and suggest thoughts thereon, that seem to us to be as full of interest as of novelty. Only a few of these can we allude to, such as the great length of the optic nerve, which allows slack to be taken during the transfer of the eye, and yet does not cause the sight to be interfered with, and the direct and very active circulation taking place to and from the heart and the orbital cavity, constituting almost an ocular heart.

The causes usually assigned for the development of fishes with a binocular side are all more or less unsatisfactory. It is known that in experiments thereon similar conditions constantly fail to produce similar results. Of the causes assigned the chief are: that the great width of the body in flounders makes the resting on the one side the most natural position; but there are many fishes of far greater width which swim vertically. The absence of a swimming bladder has also been assigned as a good reason, but some flounders have a swim bladder. Alexander Agassiz hints that the true cause may perhaps be that some broad fish may find it much easier to pursue their prey while swimming close to the bottom. They are protected from detection by their coloured side resembling sand, mud, and gravel. This would gradually lead to the exclusive use of one side (should the fish lie on either side) and would result in the atrophy of the eye, unless the fish were able to transfer his eye to the other side and so retain it. But then it will be asked, why do we not find flat fish among the broad forms of every family of fishes? and, remembering that flounders are only found in the most recent geological deposits, why were they not as common in earlier times as at the present day? and, above all, why was the tendency of the eye to change transmitted from generation to generation and not the binocular state itself?

May not, suggests Agassiz, Giards' idea come to our help here. Giards hints that the fundamental cause of all asymmetry in the animal kingdom is due to a difference in the strength of the organs of sense, and he gives in support of this idea some most ingeniously explained

cases. At any rate, the action of light upon the sense organs, which in all embryos are developed out of all proportion to their ultimate conditions, must remain an all-important element in its effect upon the nervous system. In embryos so transparent as those of many young fishes are, which might be said to be nothing but eyes, brain, and notochord, the action of light must be infinitely more potent upon their nervous system than it can possibly be in older stages, when the muscular system has assumed the control.

The pigment cells appear early in the egg. In some fishes, immediately before the little fish is hatched, two colour elements are to be found, black and yellow; but in the majority of cases the black alone is present, the yellow element appearing subsequently, and, last of all, the red. Pouchet's experiments seem to show that the blue pigments are only a dimorphic condition of the red pigments. This, by the way, would account for why a lobster turns red when cooked. The proper mixture of the three colours—black, red, yellow—enables the flounders to imitate most admirably the general effect of their feeding-grounds; so much so that often it requires a most practised eye to detect them. The rapidity with which they can change their colour is also quite striking. Agassiz frequently removed a jar containing a young flounder, which he figures, from a surface imitating a sandy bottom to one of a dark chocolate colour, and in less than ten minutes the black pigments would obtain a preponderance.

The question of the form and development of the pigment cells is also discussed in the memoir. As to the causes of colour in the animal kingdom we would seem to be only on the threshold of an interesting and novel field of inquiry, and it would seem, says Agassiz, very hazardous to infer from a physiological point of view, as has been frequently done on philological grounds, that Homer's colour descriptions indicate a gradual development of the sense of colour in the early races of mankind.

E. PERCEVAL WRIGHT

Since writing the above we have received from Prof. Japetus Steenstrup "Fortsatte Bidrag til en rigtig Opfattelse af Oiestillingen hos Flyndrene," with four plates. This supplemental memoir is in Swedish, and gives a *résumé* of what has been written on the subject since the paper in which the illustrious author first called attention to it, with criticisms thereon. An advance sheet of Agassiz's paper also enabled him to quote the chief details of his observations. The memoir also contains a description with beautiful figures of a Plagusia form, which was captured while its eye was just about to traverse the head obliquely and to take its place on the other side as the upper eye. It also gives a series of figures which make clear the connection that exists between certain frequently met with monstrous forms of flat-fish and the normal forms. One of these thus illustrated is the "malformed brill" figured in Yarrel's "British Fishes."

THE BROWN INSTITUTION

IT is now just seven years since the Brown Institution was opened, under the auspices of the Senate of the University of London, as a place for the study of the diseases of animals. It was at that time placed by the Senate under the direction of a committee comprising the most eminent members of the medical profession, with Dr. Sharpey as their chairman. Dr. Burdon-Sanderson was appointed superintendent, with Dr. Klein—who had then recently migrated from Vienna to London—as his coadjutor. A hospital had been built for the reception of diseased anmals, and placed under the care of a highly qualified veterinarian, Mr. Duguid, and in connection with it a good and sufficient laboratory had been erected for the purpose of carrying out pathological and therapeutical experiments. No provision could be made from the funds of the Institution for the expenses of such investigations, it having been found necessary to devote the whole available income to the purely charitable purposes which the founder had associated with the investigation of disease in his testamentary statement of the objects he had in view. Pecuniary aid for research was, however, not wanting. The work done in the laboratory was, during the first three or four years, for the most part conducted at the instance of Mr. Simon, who was at that time at the head of the Medical Department of the Privy Council, and it was thus provided for by annual grants of public money. For a time all went on favourably, and it seemed possible that the Brown Institution would eventually fulfil the functions and acquire the importance of those State-supported establishments for research which have recently accomplished so much for the advancement of medical science in Germany. But, alas! clouds soon began to gather. That strange, popular agitation which culminated in the passing of the "Vivisection Act" showed itself to be specially hostile to those systematic experimental investigations which, at the present moment, are absolutely necessary for the elucidation of fundamental questions in pathology. Accordingly, the Brown Institution became a prominent object of attack. When the Act was passed it became apparent that the realisation of the hopes which had been entertained was no longer probable, for it was soon found that, in their bearing on pathological inquiries, the restrictions imposed really amounted to prohibitions.

These circumstances affected the working of the institution in such a way as seriously to diminish its prospect of usefulness. Early in the present year Dr. Burdon-Sanderson, baffled in his plans, resigned his appointment. His resignation has been followed by that of Mr. Duguid, who has accepted a more lucrative position under Government; and finally Dr. Klein, who became a candidate for the vacant superintendentship, and was supported by the unanimous recommendation of the Committee, but was rejected by the Senate of the University, who thus showed that the possession of an academical title confers none of the academical spirit. At the present moment, therefore, the Brown Institution is represented only by the buildings and the endowment. The men who have done its work, and whose names have been hitherto identified with it, have retired. The prospect is discouraging, but not quite so bad as it seems.

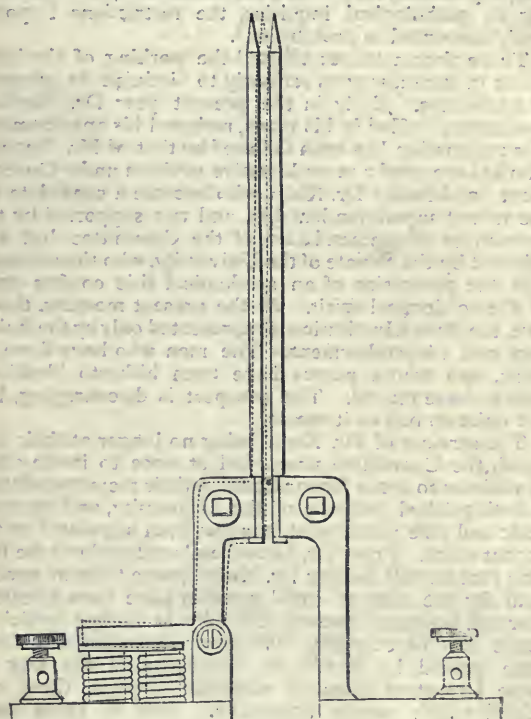
The services of Dr. Klein being no longer at their disposal, the Committee proceeded at once to invite other candidates to come forward, and on their recommendation a distinguished graduate of the University, and an energetic and able pathologist, has just been appointed to the vacant office. From Dr. Greenfield's antecedents we feel sure that he will (failing Dr. Klein) prove to be as good a man for the post as could possibly have been selected. Nor will he experience any difficulty in finding sufficient scope for his energies. Whatever obstacles may have been placed by ill-advised legislation in the way of some important lines of scientific inquiry, there are others which remain accessible. One of these lines was opened by Dr. Burdon-Sanderson three years ago. In the beginning of 1876 a grant of 500*l*. was made by the Royal Agricultural Society for the carrying out of scientific investigations at the Brown Institution, as to the nature and origin of some of the destructive contagious diseases of animals which prevail in this country. The results of these inquiries have already been, in part, printed, and others are in course of publication. In consequence of the resignation of Dr. Sanderson and of his veterinary coadjutor Mr. Duguid, the progress of his work has been temporarily arrested. But it is gratifying to be able to state that at the Annual Meeting of the Royal Agricultural Society which took place on

the 12th inst.; an additional sum of 250*l.* was voted for their prosecution, and that they will be actively resumed as soon as Dr. Greenfield has completed his arrangements.

The interval of inactivity has been used by the committee for carrying out important improvements of the premises in Wandsworth Road, so that Dr. Greenfield will enter on his new duties with many advantages in his favour—an excellent laboratory, sufficient resources, fruitful work already in progress, and a committee including such men as Busk, Gull, Paget, Quain, Sharpey, and Simon to back him. We feel confident that the wisdom of the appointment will be justified by the result, and that the new chapter in the history of the Brown Institution which will begin with the year 1879, will be a successful one.

ON SOME IMPROVED METHODS OF PRODUCING AND REGULATING ELECTRIC LIGHT[1]

IN a former communication to the Society I directed attention to the fact that when the electric light is produced from the ends of two carbon pencils placed parallel to each other, if the strength of the electric current, the thickness of the carbons, and the distance between them are rightly proportioned, the carbons will burn steadily downwards until they are wholly consumed, without any insulating material between them. To initiate the light by this method, it is necessary to complete



the electric circuit between the carbons by means of some conducting substance, which volatilises on the passage of the current, and establishes the electric arc between the points.

When a number of such lights are produced simultaneously from the same source of electricity, any interruption in the continuity of the current extinguishes all the lights in the same circuit, and each pair of carbons requires to be reprimed before the lights can again be established. This defect, as will be obvious, would cause great inconvenience when the lights are not easily accessible, or are at considerable distances apart.

In the course of my experiments it was observed that when the electric circuit was completed at the bottom of a pair of carbons close to the holders, the arc immediately ascended to the points, where it remained so long as the current was transmitted. My first impression of this peculiar action of the arc was, that it was due to the ascending current of hot air by which it was surrounded. This, however, was found not to be the cause, as the arc travelled towards the points in whatever position the carbons were placed, whether horizontally or vertically in an inverted position. Moreover, when a pair of carbons were held in the middle by the holders, the arc travelled upwards or downwards towards the points, according as the circuit was established above or below the holders. The action was, in fact, recognised to be the same as that which determines the propagation of an electric current through two rectilinear and parallel conductors submerged in contact with the terrestrial bed, which was described by me in the *Philosophical Magazine*, August, 1868.

In all the arrangements in general use for regulating the electric light, the carbon pencils are placed in the same straight line, and end to end. When the light is required, the ends are brought into momentary contact, and are then separated a short distance to enable the arc to form between them. The peculiar behaviour of the electric arc when the carbons are placed parallel to each other, suggested to me the means of lighting the carbons automatically, notwithstanding the fact that they could only be made to approach each other by a motion laterally, and to come into contact at their adjacent sides. To accomplish this object, one of the carbon holders is articulated or hinged to a small base plate of cast iron, which is so constructed as to become an electro-magnet when coiled with a few turns of insulated wire. The carbon holder is made in the form of a right-angled lever, to the short horizontal limb of which is fixed an armature placed over the poles of the electro-magnet. When the movable and fixed carbon holders are brought into juxtaposition, and the carbons inserted in them, the upper parts of the two carbons are always in contact when no current is transmitted through them, as shown by the dotted lines in the engraving.

The contact between the carbons is maintained by means of an antagonistic spring inserted in a recess in one of the poles of the electro-magnet, and reacting on the under side of the armature. One extremity of the coil of the electro-magnet is in metallic connection with the base of the carbon holder, while the other extremity of the coil is in connection with the terminal screw at the base of the instrument from which it is insulated. The coils of the electro-magnet are thus placed in the same circuit as the carbon pencils.

When the alternating current from an electro-magnetic induction machine is transmitted through the carbons, the electro-magnet attracts the armature and separates the upper ends of the carbons, which brings them into their normal position, and the light is immediately produced. When the circuit is interrupted, the armature is released; the upper ends of the carbons come into contact, and the light is produced as before. When several pairs of carbons are placed in the same circuit, they are, by this arrangement, lighted simultaneously.

H. WILDE

[1] Supplement to Paper read at the Manchester Literary and Philosophical Society, November 26 (see NATURE, vol. xix. p. 78). Communicated by the Author.

INFLUENCE OF THE STRAITS OF DOVER ON THE TIDES OF THE BRITISH CHANNEL AND THE NORTH SEA[1]

THE conclusions are:—

1. The rise and fall of the water-surface and the tidal streams throughout the North Sea north of the

[1] Abstract of a paper read at the Dublin meeting of the British Association.

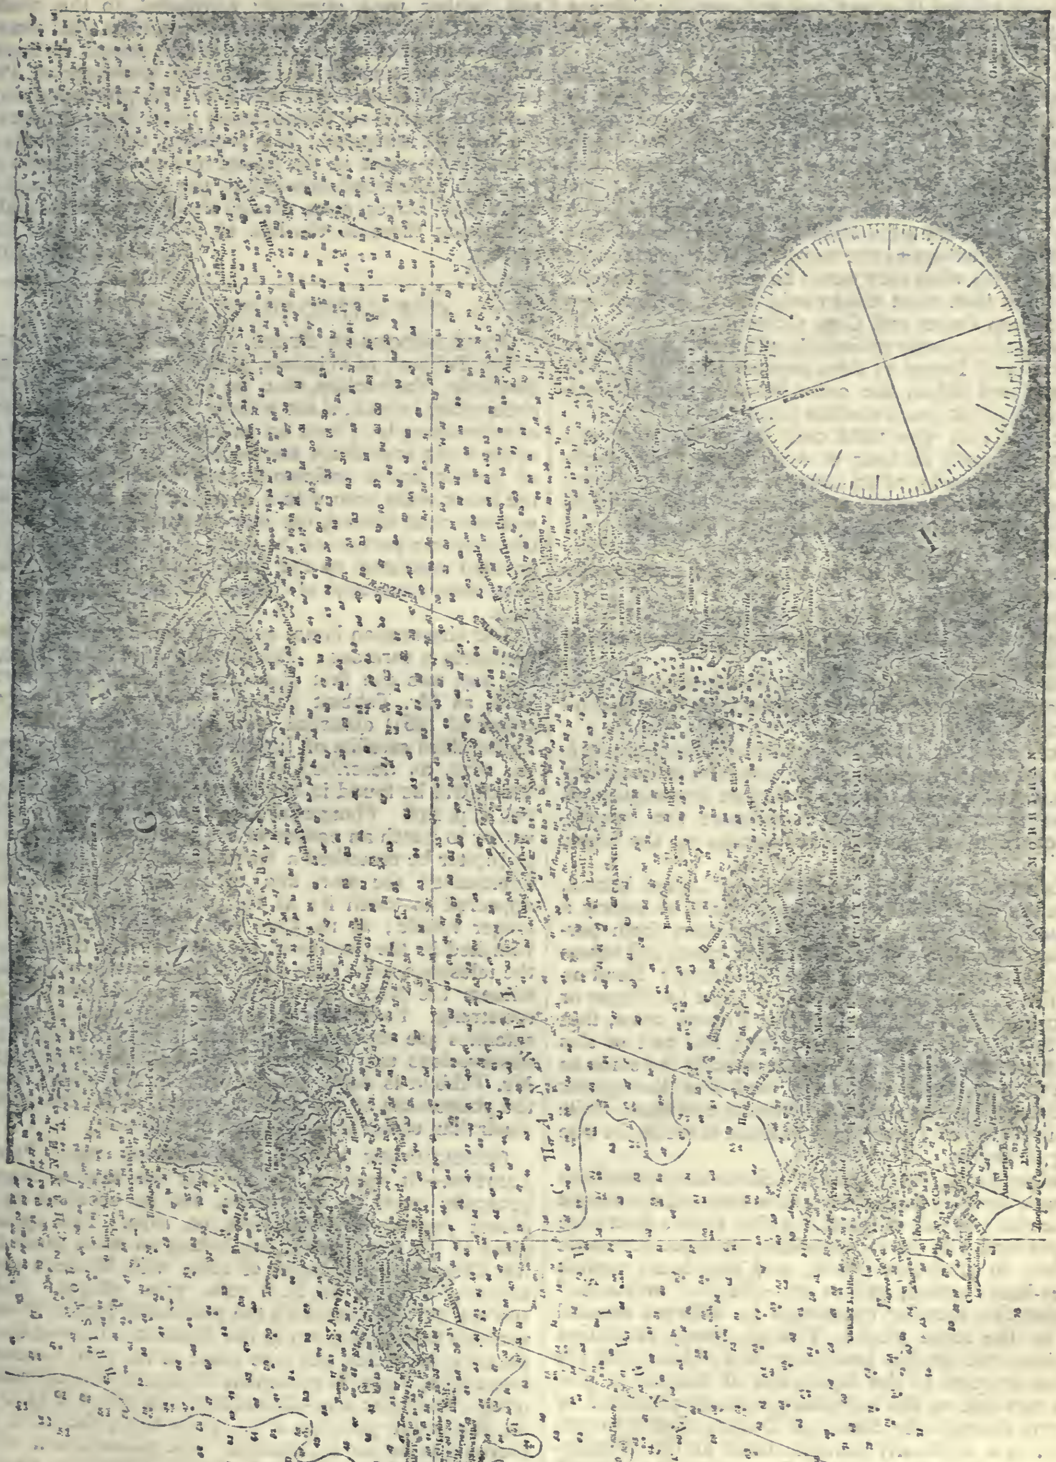


CHART OF THE ENGLISH CHANNEL.

parallel of 53° (through Cromer, in Norfolk) and the north coast of Holland and Hanover, are not sensibly different from what they would be if the passage through the Straits of Dover were stopped by a barrier.

2. The main features of the tides (rise and fall and tidal streams) throughout the British Channel west of Beachy Head and St. Valery-en-Caux do not differ much from what they would be if the passage through the Straits were stopped by a barrier between Dover and Cape Grisnez (Calais).

3. A partial effect of the actual current through the Straits is to make the tides throughout the Channel west of a line from Hastings to the mouth of the Somme more nearly agree with what they would be were there a barrier along this line than what they would be if there were a barrier between Dover and Cape Grisnez.

4. The chief obviously noticeable effect of the openness of the Straits of Dover on tides west of Beachy Head is that the rise and fall on the coast between Christchurch and Portland is not much smaller than it is.

5. The fact that the tidal currents to the westward commence generally an hour or two before Dover high-water and to the eastward an hour or two before Dover low-water instead of exactly at the times of Dover high- and low-water, is also partially due to the openness of the Straits of Dover.

6. The facts referred to in Nos. 4 and 5 are wholly due to three causes :—

(1) The openness of the Straits of Dover.

(2) Fluid friction (in eddies along the bottom and in tide-races).

(3) Want of absolute simultaneity in the time of high-water across the mouth of the Channel from Land's End to Ushant.

It is certain that (1) is very sensibly influential; it is probable that (2) is also so; it is possible, but scarcely probable, that (3) is so. Without farther investigation it would be in vain to attempt to estimate the proportionate contributions of the three causes to the whole effect.

7. It is certain that were the Straits of Dover barred, and were the water frictionless, there would be nearly a perfect *nodal line* [with but a small deviation from perfect nodality because of the influence of cause (3)] across the Channel from somewhere near St. Alban's Head on the English coast to somewhere near Cape La Hague or Cherbourg or Cape Barfleur, on the French coast, that west of this line the time of low-water, and east of this line the time of high-water, would be exactly the same as the time of high-water at Dover; and that throughout the Channel the water would be flowing eastwards while the tide is rising at Dover, and westwards while the tide is falling at Dover.

8. (Understanding from Fourier's elementary principles of harmonic analysis that all deviations from regular simple harmonic rise and fall of the tide within twelve hours are to be represented by the superposition of simple harmonic oscillations in six-hours period, and four-hours period, and three-hours period, and so on—like the "overtones" which give the peculiar characters to different musical sounds of the same pitch.) The six-hourly oscillation which gives the double low-water at Portland and the protracted duration of the high-water at Havre[1] is probably in part due to the complex-harmonic character of the current through the Straits of Dover; that is to say, definitely, to a six-hourly periodic term in the Fourier-series representing the quantity of water passing through the Straits per unit of time, at any instant of the twelve hours.

The double high-water experienced at Southampton, and in the Solent, and at Christchurch and Poole, and still further west, generally attributed to the doubleness of the influence experienced from the tidal streams on the two sides of the Isle of Wight, seems to have a continuity of cause with the double low-water at Portland, which is certainly allied to the protracted high-water of Havre—a phenomenon quite beyond reach of the Solent's influence. It is probable, therefore, that the double high-water in the Solent and at Christchurch and Poole is influenced sensibly by the current through the Straits of Dover, even though the common explanation attributing them to the Isle of Wight be in the main correct.

WILLIAM THOMSON

[1] At Havre, on the French coast, the high-water remains stationary for one hour, with a rise and fall of three or four inches for another hour, and only rises and falls thirteen inches for the space of three hours; this long period of nearly slack water is very valuable to the traffic of the port, and allows from fifteen to sixteen vessels to enter or leave the docks on the same tide.

OUR ASTRONOMICAL COLUMN

OCCULTATIONS OF STARS BY JUPITER'S SATELLITES.—Mr. Tebbutt, of Windsor, N.S.W., writes to the *Astronomische Nachrichten*, that on October 5 he made "an observation, which, if not without a parallel in the annals of astronomy, is at least an extremely rare one." A star of the ninth magnitude was occulted by the first satellite of Jupiter, under sufficiently good definition to allow of the latter being seen with a round disk: the occultation was not quite central, the star appearing to pass behind the northern portion of the disk. From the approximate position assigned to the star by Mr. Tebbutt, it must have been No. 20236 of Oeltzen's Argelander, called 9·10 mag.

The observation is not quite without a parallel, though doubtless a rare one; Flaugergues of Viviers (who, by the way, was the first discoverer of the great comet of 1811, as Mr. Tebbutt was also discoverer of the grand comet of 1861) observed an occultation of a small star by the third satellite of Jupiter on the morning of August 14, 1821, as described in a letter to Baron de Zach, which will be found in his *Correspondance Astronomique*, vol. v. p. 456. Flaugergues had proceeded to his observatory to watch an eclipse of the satellite, and on looking at Jupiter he remarked a small star near it; the satellite approached the star, and at 1h. 47m. sidereal time, appeared to touch it; at 1h. 56m. 52s. the star was no longer visible; at 1h. 59m. 10s. the satellite in its turn vanished in the shadow of the planet. He continued at the telescope some time after its disappearance, hoping to witness the star's emergence, but twilight soon became too strong. Perhaps now that the phenomena of Jupiter's satellites are more closely watched than formerly, such observations may become somewhat less exceptional; Mr. Tebbutt is doing good service in the observation of the phenomena of the Jovian system, as is also another Australian observer, Mr. Todd, at Adelaide.

OCCULTATION OF 64 AQUARII BY THE PLANET JUPITER.—It appears certain that the star 64 Aquarii, generally rated $6\frac{1}{2}$ magnitude, will be occulted by the planet Jupiter on September 14, 1879. The apparent place of the star for that day, taking its mean place from the Greenwich catalogue of 1864, with Mädler's proper motion, will be in R.A. 22h. 32m. 58·45s., N.P.D. 100° 39′ 0″·6, whence, with the position of Jupiter from Leverrier's tables, as given in the *Nautical Almanac*, the apparent conjunction will take place at 1h. 53m. Greenwich mean time, when the geocentric difference of declination is 9″·8. The polar semi-diameter of the planet is 23″·0 and its horizontal parallax 2″·2. It is clear, therefore, that there must be an occultation. The phenomenon will be most favourably witnessed at the Australian observatories; at Melbourne, for instance, the planet will be only a quarter of an hour from the meridian and 27° from the zenith.

THE CONJUNCTION OF MARS AND SATURN, JUNE 30, 1879.—The *Nautical Almanac* notifies a conjunction of these planets on June 30, 1879, at 8h. G.M.T., with Mars only 1′ to the north of Saturn. It is not without interest

to examine this near approach more closely, particularly as Bouvard's Tables of Saturn were used for 1879. According to Leverrier's Tables, the position of Saturn from Bouvard requires corrections of about + 1·79s. in Right Ascension, and − 0″·4 in Declination; whence, with Leverrier's place of Mars the conjunction in right ascension occurs at 8h. 3·7m. G.M.T., and at this time the geocentric difference of declination is 1′ 29″·0. The apparent semi-diameter of Mars (taking 9″·45 for the diameter at mean distance) is 4″·46, and the apparent polar semi-diameter of Saturn, 7″·83; the horizontal parallaxes, 8″·36 and 0″·93 respectively. Hence it is evident that there will be no approach to an occultation. At conjunction the planets will be below the horizon in this country, but will be near the meridian at our Australian observatories; there, however, the least distance between the south limb of Mars and the north limb of Saturn will, according to the Tables, exceed a minute of arc. Mr. Marth has pointed out that the last close conjunction of Saturn and Mars took place on April 18, 1817; the *Berliner Jahrbuch* for that year gives the time of conjunction at 7h. M.T. at Berlin, with Mars 1′ S. of Saturn.

An occultation of Saturn by Mars, so far as we know, has not yet been put upon record, nor suspected before the invention of the telescope. The earliest mention of a near approach of the two planets is found in the Chinese annals during the latter days of the 10th moon, A.D. 27; on this occasion Mars, Jupiter, and Saturn were all situate within about 2° from the bright star Regulus; and the same annals record that on July 23, A.D. 143, Mars was very near to Saturn.

BIOLOGICAL NOTES

NATURAL SELECTION AMONG LARVAL SALAMANDERS.—Every case illustrating survival of the fittest has its own interest, as well as its bearing on general laws. The New England salamanders lay large numbers of eggs attached to water plants, and the larvæ are very interesting to watch. In a group that was studied recently, cannibal tendencies soon developed, the stronger eating off the gills of the weaker, at the same time being able to protect their own, within a week or ten days after hatching; these cannibals were fifty per cent. larger than their brethren, and, soon waxing bolder, they began to swallow them bodily. After ten days of the results of such feeding, they were ten or twelve times the size of such weaker brethren as were still left alive. Thus they rapidly developed and passed out of the gill-bearing stage. See Mr. S. F. Clarke, in *American Naturalist* for September.

THE MUSCLES OF THE MAMMALIAN FOOT.—Dr. D. J. Cunningham (*Journal of Anatomy and Physiology*, October, 1878), after dissecting the manus and pes of a large number of mammals, finds that the typical arrangement of the intrinsic muscles of the foot is the same as in the hand, and that this is best seen in certain marsupials. In these animals the muscles are disposed in three layers (1) a plantar layer of adductors; (2) an intermediate layer of short flexors; and (3) a dorsal layer of abductors. Deviations from the type may take place by suppression or by fusion of certain elements of the different layers. Fusion of the members of the intermediate and dorsal layers is very common. The presence of an opponens muscle is not accounted for in the foregoing disposition. When present Dr. Cunningham regards it as derived most commonly from the short flexor, but in many of the carnivora it proceeds from the plantar layer. Further, it is found that in many animals the relation of the intrinsic muscles to the metatarsal bones, both as regards their origin and position, corresponds with transitory conditions in the foot of the human embryo. The adult dog agrees exactly with the first stage of the human fœtus in the relation of the intrinsic pedal muscles to the metatarsals; the bones are closely compressed together, and the muscles are entirely plantar in position.

SENSITIVE ORGANS IN ASCLEPIADACEÆ.—Robert Brown gave it as his opinion, based on experience, that fertilisation in this family of plants depends largely upon insect agency. Dr. J. G. Hunt has recently published observations on *Stapelia asterias*, whose flower has an extremely disagreeable and animal odour, which appears to attract many flies. Under observation flies were seen eagerly applying their tongues all over the petals and essential organs, apparently eating, with an almost intoxicating relish, the excretion covering those parts. This banquet was indulged in with safety until their tongues came in contact with one of five black spots situated near and alternate with the stamens, when, with amazing quickness, the fly was seized and firmly held by the tongue—a hopeless prisoner. Now a struggle commenced, and if the fly was small and not vigorous, he was retained; if large and strong he escaped, dragging away the black spot and also the pollen-masses, two of which are attached to each trap. The adhesion of the fly's tongue is not caused by any viscid liquid, but by a capital pair of blades, which, when touched lightly by a fly, or even a hair, close instantaneously, and secure the object. Two species of Asclepias have been examined by Mr. Edward Potts, and in these he finds that each anther has a pair of sacks or cases in which the pollen masses are suspended so as to make their withdrawal easy. They are closely adherent to the stigma. The sensitive glands are placed in shallow depressions upon the perpendicular columnar ridges of the stigma. The fact of the removal of the pollen masses by insect agency is well known; the question to determine was whether the glands had anything to do with the removal. Mr. Potts caught house-flies and held them by their wings above the flowers, allowing their feet to scramble over them. Almost immediately one or more of these would become ornamented with groups of the glands and pollen-masses, which clung so closely that their later struggles and rubbings failed to detach them. When separate hairs were directed on to a gland, the latter instantly contracted and clung to the hair, tearing itself loose from the stigma, and carrying away the pollen masses with it. On one of the species of Asclepias Mr. Potts noticed three flowers which, in addition to its own complete anthers, had one other sensitive gland and its attached pollen-masses, inserted under the edge of a normal anther, and against the sloping lower surface of the stigma. The development of these adventitious pollen-masses was traced till they put forth a profusion of pollen-tubes into the stigma, and the ovaries began to increase in size. Dr. Asa Gray mentions self-fertilisation as occurring in this genus by a similar growth of bundles of pollen-tubes penetrating the stigma at its lower extremity. But here in the presence of the foreign pollen-masses none of the home-grown ones had put forth pollen-tubes. It is conjectured that the maturity of the pollen-masses is reached so late that the stigma of the same flower is frequently unsusceptible. But if the pollen-masses from earlier flowers are removed by insects and lodged upon another just opened, they develop pollen-tubes, and cross-fertilisation ensues. Thus the sensitive glands are not for capture of insects, but to favour cross-fertilisation. (*Proceedings*, Acad. Nat. Sci. Philadelphia, 1878).

THE INHALATION OF PHOSPHURETTED HYDROGEN.—Dr. T. B. Henderson, of Glasgow (*Journal of Anatomy and Physiology*, October, 1878), has investigated the physiological effects of the inhalation of phosphuretted hydrogen gas, by inclosing an animal in an air-tight chamber of known capacity, and subsequently introducing into this a given quantity of the gas. In the first experiment a strong rat was placed in an atmosphere consisting almost entirely of phosphuretted hydrogen, and death

occurred in about ten minutes. An atmosphere containing one per cent. of the gas was found to prove fatal within half an hour. In the case of a large female rabbit, 0·2 per cent. caused death in thirty-three minutes. In these cases the most marked symptom was that of great increase in the number of respirations. Before death, respiration became slow and laboured, and convulsions resembling those of opisthotonus occurred. The ventricles of the heart became most powerfully contracted. Where the strongest dose was administered, the effect on the heart was most marked, and the lungs appeared unaffected. When small quantities of the gas were used, within a very short time the animals began to show signs of suffering from intense irritation of the skin, scratching and biting at it incessantly. Afterwards the creatures seemed to become drowsy, and assumed a very peculiar attitude, sitting down on all-fours, the back bent upwards, and nose pushed backwards between the fore-paws, so as to bring the forehead against the floor of the cage; a rat in this position looked very much like a curled-up hedgehog. A fatal result occurred when the quantity of gas was so small as 1 to 5120. In no case could the odour of the gas be detected in any organ of the body after death. The gas did not appear to exert any local action on the skin.

STRUCTURE AND AFFINITIES OF CHARACEÆ.—This difficult problem has been the subject of recent discussion in the pages of Trimen's *Journal of Botany*. The first paper was in the July number, by Mr. A. W. Bennett, who gave his reasons for dissenting from some generally accepted views of the structure of *Chara*, and from its assignment by Sachs to a place among the Carposporeæ. He objects in the first place to the use of the term "pro-embryo" (Vorkeim) for the immediate product of the germination of the spore, the homologue of the protonema of a moss, and not of the pro-embryo nor suspensor of Selaginellaceæ and Phanerogams. The term sporangium is also frequently misapplied to the nucule, which is in reality an archegonium. The so-called "sporocarp" is formed before and not as the result of fecundation. Finally, Mr. Bennett maintains that Characeæ differ from all the other higher cryptogams in the absence of any alternation of generations, the nearest affinity being with Muscineæ, which they approach in their organs of reproduction. In the September number Prof. Caruel expresses his agreement with Mr. Bennett in removing the Characeæ from the Carposporeæ, but differs in his interpretation of the structure which is the immediate product of germination, the homology of which with the protonema of mosses he contests. He places them in a separate class of their own, intermediate between phanerogams and vascular cryptogams. Finally, in the number for December, Mr. S. H. Vines has a very elaborate essay on the subject. He agrees with both the previous writers in separating the Characeæ from the Carposporeæ, and with Caruel in disputing the homology of the "pro-embryo" with the protonema of a moss, but on the other hand again considers their nearest affinity, though remote, to be with Muscineæ. His principal object is to show that the "pro-embryo" is in reality the embryo of the plant, and that it constitutes in itself the non-sexual generation or sporophore, homologous with the sporogonium of mosses, notwithstanding the apparently anomalous fact that it never produces spores. For such a structure he proposes the term "aposporous sporophore," and compares it to the "apogamous" oophore or prothallium of *Pteris cretica* and some other ferns, which are anomalous in not producing sexual organs of reproduction.

GEOGRAPHICAL NOTES

THE fifty-sixth supplement to Petermann's *Mittheilungen* has just been published, and consists of a masterly treatise on Deltas, by Dr. G. A. Credner, of Halle. The author shows the importance of deltas in reference both to geography and geology, and discusses carefully the real import of the term. He then, in the first part of his work, treats of the Formation, Structure, Growth, and Distribution of Deltas under the heads of (1) Limit and Form of the Delta; (2) Formation and Condition of the Delta Surface; (3) Size of the Delta; (4) Its Power; (5) Its material; (6) Architecture; (7) Rate of its Growth; (8) Results of its Growth; (9) The Age of Deltas; (10) Number and Geographical Distribution of Deltas; (11) Classification of Deltas. The second part treats of the various causes of the origin of deltas, the causes and conditions of their formation, in which the author discusses various processes of great geological interest. Three sheets of maps accompany this most important paper, showing, among other points, the various deltas of the world.

WE are glad to learn of the early appearance of a work published in Russia under the editorship of M. Semenoff, President of the Geographical Society at St. Petersburg. The title is "Illustrated Russia," and it will give a geographical, historical, ethnographical, and statistical description of the country. We notice among the very numerous collaborators all the names well known in the Russian geographical world. The work will contain four folio volumes of sixty to seventy sheets each, and it will be accompanied with numerous illustrations, engraved by the best European firms. Another work of the same kind is undertaken by M. Mordovtseff—"The Ukraine (Little Russia): its History and its People." It will be on the same plan as the well-known work on "Bohemia: its History and its People."

WE are also glad to notice the appearance of the last volume of the "Works of the Ethnographical Expedition sent by the Russian Geographical Society." This volume deals with the south-western provinces of Russia. The expedition was undertaken in 1869, finished in two years, and the printing of the reports, which occupy seven large volumes, has taken since 1872.

WE find in the *Izvestia* of the Russian Geographical Society a notice of the journey of M. Mayeff in Southern Bokhara, last August. After having reached Karshi with an embassy sent to the Emir by the Governor-General of Tashkent, M. Mayeff visited the mountain pass, Ak-bash, which goes from Tenga-khoram to the Kerchak River, and to the great and wealthy village, Kuitan: thence he proceeded by the pass Tenga-daval to Shir-abad. The Kerchak River and its tributary, Kuitan-daria, both mighty mountain streams, were previously quite unknown. The Tenga-daval cleft cuts through the whole mass of the Kuityn-tau, the south-western part of Hissar ridge. From Shir-abad M. Mayeff, going further south, crossed the great Pashkhund ridge, reached the Surkhan river at Kakaity, and traced its banks down to Regar and Sary-djuy. Thence he returned to Shahri-sabs by a very bad route, hardly practicable even on horseback, along the rocky banks of the wild stream, Sengri-dagh. The surveys made during this journey are a most important acquisition for the geography of Central Asia; the highlands of Bokhara, quite unknown until now, will soon receive on our maps an outline in accordance with nature.

THE last number of the *Izvestia* of the Russian Geographical Society contains a report, by Capt. Sidensner, on the possibility of a water communication between the tributaries of the Obi and Yenissei; a very interesting paper, by M. Miclucho Maclay, on the Pelew archipelago, being a description of the people, its customs, administration, and religion; a necrology of M. Chaslavsky; and several notes:—On M. Mayeff's journey to Southern Bokhara, on the Russian cruises to the Obi and Yenissei, and especially statistical ones on printing in Moscow, on trade, ports, and telegraphs in Japan, and on the population and manufactures in governments Tula and Nijni-Novgorod.

DR. EDWIN R. HEATH, to whom we referred some time ago as intending to take up the work of South American exploration commenced by Prof. Orton, and interrupted by his untimely death, left New York on November 18, on the *William H. Keeney*, for Pará, expecting to proceed by steamer to San Antonio, to remain there during the winter, and from that point as a centre to carry on his further investigations. In these he expects to be greatly assisted by Messrs. T. and P. Collins, of Philadelphia, the contractors for the Mamore and Madera Railroad.

THE Woodruff half-educational, half-pleasure expedition round the world has been again organised on a new basis. A steamer of 3,000 tons has been purchased in Europe, and the inclusive fare is 2,500 dollars.

MR. S. E. PEAL communicates to the *Indian Tea Gazette* some remarks on the subject of an overland route to China, *viâ* the Assam Valley, which are of interest, as there is no attempt to under-rate the great difficulties to be encountered. He justly observes that the merits of the various passes out of Eastern Assam are not well understood, and that it is comparatively easy to draw a line on the map from some point in Upper Assam to the Yangtoze or Likiang-fu, and to say, "Why cannot this be done?" Wilcox and others since have sufficiently shown the difficult nature of the country, *viâ* the Tengapani and the Brahmaputra Valley; what lies beyond the point explored is reputed still worse, and as crossing snow. Northwards again, *viâ* the Dihong, or Dihong Gorges, the outlet is equally uninviting. The Upper Subansire, or Lopra-cha-chu, is not well explored, though routes not far from it are known to pass for three-quarters of a mile along the face of a precipice 1,500 feet above an abyss, and on a path of stone slabs resting on iron piers let into the face of the rock. The Towang route is, again, difficult, and too far west. South of the Tengapani we have Dapha Búm, 14,500 feet high, with a pass to the south, in which Wilcox's experiences prove how unsuitable it would be for a trade-route. South of Daphapani is the upper portion of the Buri Dihing, and whether there is a route up it crossing Eastern Patkai and going down the Sitka, is not known, though Singphús travel that way. It is one of the routes to be explored, and may give a pass at, perhaps, 5,000 feet elevation or less. The Namrup basin, however, would so far seem to be the only reliable and easy outlet from Eastern Assam: and here is a pass at an elevation of about 1,000 ft., leading *viâ* Hukong and the Shoemai direct to Western Yünnan, a route which is at present in use. By the Patkai route past Nongyang Lake to the Hukong Valley, Mr. Peal says, we cross at the highest an elevation of 1,500 to 2,000 ft., and fall at once into a beaten track to Yünnan. By this route alone also can the huge snow-clad ridges be turned that stand as barriers east and west of the Upper Irrawadi or Shoemai, and that stretch down from the north to about the parallel of 27°. In point of fact the east-south-east is the only direction in which it is possible to get out of Assam in the direction of China at less than 2,000 ft. above the sea-level.

THE COMPOUND NATURE OF THE ELEMENTS

WE have not yet received from the Royal Society the paper read last Thursday by Mr. Lockyer, in which he brought forward facts indicating the compound nature of the chemical elements. In the meantime the following article from yesterday's *Times* may be of interest; it is evidently written by a chemist who was present when the paper was read:—

"At a crowded meeting such as is seldom witnessed of the Royal Society, on Thursday evening last, Mr. J. Norman Lockyer, F.R.S., read a lengthy paper, in which he discussed the evidence derived from spectroscopic observation of the sun and stars and from laboratory experiments, which has led him to the conclusion that the so-called elements of the chemist are in reality compound bodies. In order that the line of argument followed by Mr. Lockyer may be understood, it will be necessary briefly to refer to the results of previous researches. As a rule, in observing spectra, the substance to be examined is volatilised in a gas flame or by means of sparks from an induction-coil, and the light is allowed to fall on the slit of the spectroscope; the spectrum is then generally one in which the lines run across the entire field, but by interposing a lens between the spark apparatus and the slit of the spectroscope, Mr. Lockyer was enabled to study the various regions of the heated vapour, and thus to establish the fact, already noted by some previous observers, but to which little attention had been paid, that all the lines in the spectrum of the substance volatilised did not extend to equal distances from the poles. He then showed by the aid of this method that in the case of alloys containing different proportions of two metals, if the one constituent were present in very small quantity, its spectrum was reduced to its simplest form, the line or lines longest in the spectrum of the pure substance alone appearing, but that on increasing the amount of this constituent its other lines gradually appeared in the order of their lengths in the spectrum of the pure substance. Similar observations were made with compound bodies. It was also noticed that the lines furnished by a particular substance varied not only in length and number, but also in brightness and thickness, according to the relative amount present. Armed with these facts, and with the object of ultimately ascertaining, more definitely than has hitherto been possible, which of the elements are present in the sun, Mr. Lockyer, about four years ago, commenced the preparation of a map of a particular region of the spectra of the metallic elements, for comparison with the map of the same region of the solar spectrum. For this purpose about 2,000 photographs of spectra of all the various metallic elements have been taken, and, in addition, more than 100,000 eye observations have been made. As it is almost impossible to obtain pure substances, the photographs have been carefully compared, in order to eliminate the lines due to impurities; the absence of a particular element as impurity being regarded as proved if its longest and strongest line was absent from the photograph of the element under examination. The result of all this labour, Mr. Lockyer states, is to show that the hypothesis that identical lines in different spectra are due to impurities is not sufficient, for he finds short line coincidences between the spectra of many metals in which the freedom from mutual impurity has been demonstrated by the absence of the longest lines. He then adds that, five years ago, he pointed out that there are many facts and many trains of thought suggested by solar and stellar physics which point to another hypothesis—namely, that the elements themselves, or, at all events, some of them, are compound bodies. Thus it would appear that the hotter a star the more simple is its spectrum; for the brightest, and therefore probably the hottest stars, such as Sirius, furnish spectra showing only very thick hydrogen lines and a few very thin metallic lines, characteristic of elements of low atomic weight, while the cooler stars, such as our sun, are shown by their spectra to contain a much larger number of metallic elements than stars such as Sirius, but no non-metallic elements; and the coolest stars furnish fluted band-spectra characteristic of compounds of metallic with non-metallic elements and of non-metallic elements. These facts appear to meet with a simple explanation if it be supposed that as the temperature increases the compounds are first broken up into their constituent "elements," and that these "elements" then undergo dissociation or decomposition into

"elements" of lower atomic weight. Mr. Lockyer next considers what will be the difference in the spectroscopic phenomena, supposing that A contains B as an impurity and as a constituent. In both cases A will have a spectrum of its own. B, however, if present as an impurity, will merely add its lines according to the amount present, as we have above explained; whereas if a constituent of A it will add its lines according to the extent to which A is decomposed and B is set at liberty. So that as the temperature increases the spectrum of A will fade if A be a compound body, whereas it will not fade if A be a true element. Moreover, if A be a compound body, the longest lines at one temperature will not be the longest at another. The paper chiefly deals with a discussion from this point of view of the spectrum of calcium, iron, hydrogen, and lithium, as observed at various temperatures; and it is shown that precisely the kind of change which is to be expected on the hypothesis of the non-elementary character of the elements has been found to take place. Thus each of the salts of calcium, so long as the temperature is below a certain point, has a definite spectrum of its own, but as the temperature is raised the spectrum of the salt gradually dies out and very fine lines due to the metal appear in the blue and violet portions of the spectrum. At the temperature of the electric arc the line in the blue is of great intensity, the violet H and K lines, as they are called, being still thin; in the sun the H and K lines are very thick, and the line in the blue is of less intensity than either, and much thinner than in the arc. Lastly, Dr. Huggins's magnificent star photographs show that both the H and K lines are present in the spectrum of *a* Aquilæ, the latter being, however, only about half the breadth of the former; but that in the spectrum of *a* Lyræ and Sirius only the H line of calcium is present. Similar evidence that these different lines may represent different substances appears to be afforded by Prof. Young's spectroscopic observations of solar storms, he having seen the H line injected into the chromosphere seventy-five times, the K line fifty times; but the blue line, which is the all-important line of calcium at the arc-temperature, was only injected thrice. In the spectrum of iron two sets of three lines occur in the region between H and G which are highly characteristic of this metal. On comparing photographs of the solar spectrum and of the spark taken between poles of iron, the relative intensity of these triplets is seen to be absolutely reversed; the lines barely visible in the spark photograph being among the most prominent in that of the solar spectrum, while the triplet, which is prominent in the spark photograph, is represented by lines not half so thick in the solar spectrum. Prof. Young has observed during solar storms two very faint lines in the iron spectrum near G injected thirty times into the chromosphere, while one of the lines of the triplet was only injected twice. These facts, Mr. Lockyer contends, at once meet with a simple explanation if it be admitted that the lines are produced by the vibration of several distinct molecules.

"The lithium spectrum exhibits a series of changes with a rise of temperature precisely analogous to those observed in the case of calcium.

"In discussing the hydrogen spectrum, Mr. Lockyer adduces a number of most important and interesting facts and speculations. It is pointed out that the most refrangible line of hydrogen in the solar spectrum, *h*, is only seen in laboratory experiments when a very high temperature is employed, and that it was absent from the solar protuberances during the eclipse of 1875, although the other lines of hydrogen were photographed. This line also is coincident with the strongest line of indium as already recorded by Thalén, and may be photographed by volatilising indium in the electric arc, whereas palladium charged with hydrogen furnishes a photograph in which none of the hydrogen lines are visible. By employing a very feeble spark at a very low pressure the F-line of hydrogen in the green is obtained without the blue and red lines which are seen when a stronger spark is used, so that alterations undoubtedly take place in the spectrum of hydrogen similar to those observed in the case of calcium. In concluding this portion of his paper Mr. Lockyer states that he has obtained evidence leading to the conclusion that the substance giving the non-reversed line in the chromosphere, which has been termed *helium*, and not previously identified with any known form of matter, and also the substance giving the 1,474 or coronal line, are really other forms of hydrogen, the one more simple than that which gives the *h*-line alone, the other more complex than that which gives the F-line alone.

"There can be no question that the facts brought forward by Mr. Lockyer are of the highest importance and value, and that they will have much influence on the further development of spectrum analysis, to which he has already so largely contributed. But his arguments are of a character so totally different from those ordinarily dealt with by chemists that they will hesitate for the present to regard them as proof of the decomposition of the elements until either they are assured by competent physicists that they cannot be explained by any other equally simple and probable hypothesis, or until what Mr. Lockyer has foreshadowed as taking place to such an extent in other worlds has been realised beyond question or cavil in our own laboratories. It has been suggested that the same molecule may be capable of vibrating in different ways at different temperatures, and thus of yielding different spectra, just as a bell may give out different notes when struck in different ways; and although Mr. Lockyer has replied to this objection, it can scarcely be regarded as finally disposed of. The fact, however, as Mr. Lockyer has pointed out, that the change from the spectrum of a compound to the lowest temperature spectrum of its metallic element is of a similar character to and even less in degree than the change from the lowest temperature spectrum of the metal to the spectra which it furnishes at higher temperatures does not appear to favour such an hypothesis, and from the similarity in the phenomena it is difficult to deny that in both cases decomposition does not equally take place. Prof. Young's observations on the injection of particular lines into the chromosphere during solar storms are also difficult to reconcile with this view, and if the conclusions drawn from previous researches are correct, it also does not account for the short line coincidences which led Mr. Lockyer to his hypothesis.

"Chemists are careful to teach that what are at present regarded as elements are not necessarily simple bodies, but merely substances which they are unable to decompose or which they have no special reason to regard as compound bodies. The remarkable relations, both in atomic weight and properties, existing between many of the elements, tend, indeed, to show that they are related in the manner Mr. Lockyer supposes. We sincerely hope that he will continue his researches in this direction, and we trust that at no very distant time he may be able to bring forward evidence sufficiently clear to convince even the most sceptical."

NOTES

MR. J. M. WILSON, Mathematical Master at Rugby School, has been elected Master of Clifton College, in place of Dr. Percival, elected President of Trinity College, Oxford. Mr. Wilson has done very much for science at Rugby, and, although Dr. Percival is a difficult man to follow, and has done more probably than any head master for the teaching of science in schools, still we hope that Mr. Wilson will prove a worthy successor to him.

We are indebted to the kindness of Prof. Hayden for the following observation made by his party on the day of the last eclipse of the sun:—"Washington, D. C., November 18, 1878. Observation on total eclipse of the sun. Camp No. 4, Little Sandy, Wyoming Terr., July 29, 1878:—

	m.	sec.
Time of total eclipse as taken by A. D. Wilson with telescope and theodolite	2	27·5
Mr. James Eccles, with smoked glass	2	26·0
W. H. Holmes, with smoked glass and telescope of theodolite	2	27·0

	°	′	″
Approximate latititude	42	8	25
,, longitude	109	9	52

The weather was very clear and quite calm during eclipse, but was preceded by a heavy wind."

At the recent meeting of the United States National Academy, we learn from *Science News* (the third number of which has reached us), Prof. Davidson incidentally announced that he hoped to be able to observe the intra-Mercurial planets without waiting for eclipses.

The *Japan Mail* states that an astronomical observatory is to be established within the precincts of the Geographical Bureau of Tokio. The same journal also announces that telegraphic insulators, made at the village of Imari, in the province of Hizen, are of such good quality that they find large sale in Europe.

A scheme for the extension of meteorological observations throughout Russia is now being discussed by the Russian government. The Central Meteorological Institution will be located at St. Petersburg. Provincial meteorological institutions will be created in connection with each Russian university, and these provincial institutions will have under their superintendence all meteorological stations of their respective districts, which stations will be largely increased in number.

We are informed that the Government of New South Wales has requested Mr. William Forster, Agent-General for the Colony, Prof. Liversidge, of the University of Sydney, and Mr. E. Combes, M.P., C.M.G., to collect information in the United Kingdom and on the Continent relative to the working of English and foreign technological museums and colleges, with a view to forming similar institutions in Sydney. A sum of money has been placed on the Estimates by the Government of the Colony, to enable the Committee to purchase suitable specimens. We have no doubt that the Agent-General for New South Wales (3, Westminster Chambers, S.W.) will be extremely glad to receive from such institutions, or from any other source, reports or any information which would assist the Committee in its inquiries.

A correspondent writes:—A singular project is on foot at Paris. M. Camille Flammarion, having published a number of articles to prove that the moon is not destitute of inhabitants, has been led to the idea of constructing a refracting telescope which will be powerful enough to see them. He is now busy organising a committee to collect the necessary funds.

An unexpected difficulty has stopped the construction of the works for the mounting of the great refractor at the Paris Observatory. This instrument is to be erected on the grounds which the Municipal Council had let to M. Leverrier for the nominal sum of 100 francs a year for a period of ninety-nine years. But there is a law that the Government funds cannot be spent for building purposes, except on grounds belonging to the Government; and the Municipal Council, who were so liberal as to the rent, want a high price for the ground.

M. Lockroy, the editor of the *Rappel*, and representative in the French Chamber of Deputies, has introduced a bill to dispose of the money intended to be spent on the rebuilding of the Tuileries Palace, for the completion of the isolation of the French national library.

General Myer has sent orders to Sergeant Jennings to leave in Europe the collections of the works published by the Signal Corps Central Office at Washington, exhibited at Paris. This valuable set has been deposited in the hands of M. Jarry, 46, Boulevard Magenta, Paris, one of the most active members of the Meteorological Society of France, who will be ready to give any information relating to them. It is expected that the series of publications of the United States Signal Corps will be exhibited next spring at the Palais de l'Industrie, in the scientific exhibition, and an improved weather indicator will be sent from Washington to be practically tested by predictions adapted to the peculiarities of the French climate.

We notice the appearance of a Russian work, by M. Starchevsky—"Guide for the Russian in Central Asia"—being a collection of vocabularies of the languages, viz., Turkish (Djagatay, or Uzbeck), with an indication of the variations afforded by the Kashgar, Khiva, and Turkoman idioms; Kirghiz; Tartarian (Kazan and Orenburg idioms); Sart, or the town Uzbeck; and Tadjik (Bukhara idioms). The vocabularies also contain sketches of the grammars of these languages, the words being given in their Russian transcription. A second volume, containing the Russian, Uzbeck, Kirghiz, Tartar, and Tadjik part, will appear shortly.

It is probably now only a question of time for the electric light to become an everyday institution in our large towns. For several nights satisfactory experiments have been made on Holborn Viaduct, and, under most unfavourable atmospheric conditions, part of the Thames Embankment was illuminated the other evening.

In Mr. A. S. Wilson's "Experiments on Turnip Seeds" (reprinted from the *Transactions* of the Botanical Society of Edinburgh), he follows out Darwin's idea that "heavy and fine seeds tend to yield the finest plants." Mr. Wilson's conclusions are altogether in harmony with those of Darwin. The mean of a large number of experiments gave a product of 2 lbs. 7 oz. per seed in the case of large seeds, as against 2 lbs. 1¼ oz. in the case of small seeds.

In his just published report on the trade of Chinkiang, on the Yangtsze-kiang, H.M.'s Consul mentions that there are rumours that the coal, iron, and plumbago mines in that neighbourhood are to be opened without delay, under the auspices of the Viceroy, Li Hungchang. A British engineer in the employ of the Chinese Government has recently visited these mines and reported on them to the Viceroy Shên, at Nanking.

The limit of permanent snow in the Caucasus is very variable, this mountain-group, of 156 geographical miles, lying between two seas and several steppe-regions, being consequently subject to the most opposite meteorological conditions. The average height of the snow-line on the Elburs, the highest point of the Caucasus, is 10,885 feet. The average height of the lower limits of the glaciers on the Elburs is 8,216 feet. The Kasbek is the centre of another region of glaciers and permanent snow-fields, in which the true situation of the snow-line is not yet accurately ascertained. A third region comprises the high ranges of the schist-system of Perikitel and Bogoz in Daghestan. The fourth region is the Schathdag, south of Daghestan, ten geographical miles from the Caspian Sea. In this last region the snow-limit reaches to 10,374 English feet above the sea-level. The average height of the snow-limit within the Caucasus is 10,600 feet. Local variations upwards and downwards are frequent, and there may be a difference of 3,200 feet between the maximum and the minimum. In the West Caucasian regions these conditions

resemble those of South Europe; in the Eastern region they offer an analogy with those of Asiatic mountain-groups, influenced by a continental climate. During the last few years some glaciers in the western half of the Caucasus have been retrograde, just as it has been observed with those of the Alps during these last fifteen years. In 1849 several Caucasian glaciers were evidently advancing through ancient forests. The glacier of the Kasbek, especially of Deftoraki, after having followed for some time the general retrograde movement, lately began to move forward again. Experience has proved, that, whenever this movement reaches a certain amount, the end of the glacier is broken away, and may cause serious catastrophes, as it did by stopping the chief military road from Tiflis along the Terek valley to Wladikawkas. Such observations are thus of high practical importance. The Deftoraki glacier may be paralleled with the Rosenthal and Vernagt glaciers of the North Tyrol, considering their variable periods and extreme alternations of progression and retrogression. For further details we refer to Dr. Abich's paper in *Proced. Imper. Geol. Instit. Vienna*, March 5, 1878.

REPORTS come to *Science News* of a remarkable and very extensive series of caves discovered in Page county, Virginia, which, it is said, a scientific expedition will probably soon examine. Their great area, variety, curious formation, and natural ornaments, if the stories about them be true, are sufficient to place them among the wonders of the world.

WE have received Decade I. of a "Prodromus of the Zoology of Victoria, or Figures and Descriptions of the Living Species of all Classes of the Victorian Indigenous Animals," by Prof. F. McCoy (London: Trübner and Co.). The plates in this first part are most beautifully coloured, and do infinite credit to the skill of the colony. There are three plates of snakes, three of fish, one of the giant earth-worm (*Megascolides australis*, McCoy), one devoted to three species of the day-moth, and the last two to two species of diurnal lepidoptera.

THE Commission for the Survey of New York State has been reappointed with an appropriation of 14,300 dollars a year. A large amount of preliminary work has been done under Mr. J. S. Gardner.

ACCORDING to a note published by the *Norddeutsche Allgemeine Zeitung*, Berlin time will become the only one in use in the whole of the German Empire. The difference in time is thirty minutes minus on the coast of the German Ocean, and thirty-seven in advance in the eastern parts of Bavaria. This resolution has been fostered by a similar reform lately established in Sweden.

M. BARDOUX has re-organised the French Central Society of Agriculture, which will be styled the National Society of Agriculture. It will be composed of 82 ordinary members, 10 foreign members, 150 corresponding members in France and Algeria, and 50 foreign corresponding members. The President of the Republic is to be *ex officio* the patron of this Society, and the Minister of Agriculture and Trade the honorary president.

AN earthquake was felt in Cologne and vicinity on December 10 at 11.35 A.M. A similar commotion was felt in the provinces of Luxemburg and Namur, principally on the borders of the Ardennes forest; on the same day at 11.28 Brussels time. The duration of the shock was eight seconds, and it was accompanied by a well-defined noise, which awoke the inhabitants. On the following morning a meteor was observed at six o'clock in Alsatia, from Mulhausen to Colmar. A fire-ball travelling from north-west to south was seen exploding, exhibiting a display of natural fire-works. No noise was heard by any observer.

AT the last meeting of the Manchester Anglers' Association, Mr. F. J. Faraday, F.L.S., in reading a paper on the "Mind of Fishes," recounted an instance of apparent intelligence in a skate, observed by the author while officiating as curator of the Manchester Aquarium. On the occasion in question a morsel of food thrown into the tank fell directly in the angle formed by the glass front and the bottom. The skate, a large specimen, made several attempts to seize the food, but owing to the position of the mouth on the under-surface of the head, and the closeness of the food to the glass, he was unable to do so. He lay quite still for a while "as though thinking;" then, suddenly raising himself in a slanting posture, the head inclined upwards and the under-surface of the body towards the food, the creature waved his broad expanse of fins and thereby created an upward current or wave in the water, which lifted the food from its position and carried it straight into his mouth.

AT the Royal Institution a Course of Six Lectures (adapted to a juvenile auditory) on a Soap Bubble, will be given by Prof. Dewar, M.A., F.R.S., at 3 o'clock, on December 28, 31, January 2, 4, 7, 9 (1879).

ON the New Jersey bank of the Delaware River, the skeleton of a man has recently been found buried in a standing position in a red sandy bluff overlooking the stream. A few inches below the surface the neck bones were found, and below these the rest of the skeleton except the bones of the hands and feet. The skull being wanting, it could not be determined whether the remains were those of an Indian or a white man; but the burial was peculiarly aboriginal. It was found that around the lower extremities were placed a number of large stones, showing traces of fire, together with charred wood; and there was no doubt that the bones of the feet had been burnt. Probably the man had been executed as a prisoner of war, being placed erect in the pit with a fire around his feet. He would appear to have been then buried, with the exception of his head. The skeleton when complete must have been six feet high.

THE new instalment of the *Transactions* of the Asiatic Society of Japan contains several papers of considerable interest. Mr. E. M. Satow, the Japanese Secretary of H.B.M.'s Legation at Tôkiô, who was one of the earliest labourers in the field of Japanese literature, contributes articles on the "Korean Potters in Satsuma," and the "Use of the Fire-Drill in Japan;" Mr. Aston one on "Hideyoshi's Invasion of Korea," and Mr. R. W. Atkinson "Notes on the Manufacture of *Oshiroi*" (white lead). There are also two contributions on earthquakes in Japan, and notes on some of the volcanic mountains of the empire.

PEAT FUEL is much used at Bremen and in other parts of North-western Germany, and increased attention has been paid of late years to its production and preparation. We learn from Consul Ward's Report that the vast tracts of marshy moors which are to be found in many parts of the German Empire, and more especially between the River Elbe and the Dutch frontier, are regarded as containing an immense amount of wealth in the form of peat fuel. With the view of developing and improving the present means of producing and manufacturing this article, and of extending its consumption to districts where fuel is dear, an association was formed at Königsberg a few years ago, and was reconstituted last year at Schwerin. Their intention is to diffuse technical knowledge throughout the country with regard to peat production and manufacture.

THE Annual Report of the Belfast Naturalists' Field Club for 1876–77, contains a variety of matter, some of it of considerable scientific interest. There is a brief account of the excursions in connection with the Club, embracing a good deal of topographical, antiquarian, and other information. At the winter session a variety of papers were read, some of which are reported at greater or less length. In connection with Mr.

William Gault's detailed "Observations on the Geology of the Black Mountains," a coloured diagram is given. The Appendix contains papers by Mr. Joseph Wright on "Recent Foraminifera of Down and Antrim," and by Messrs. Swanston and Lapworth on the "Correlation of the Silurian Rocks of Co. Down."

THE Twentieth Report of the East Kent Natural History Society is, on the whole, satisfactory. It contains abstracts of several good papers read at the meetings. The Society has ninety-three members.

EXCAVATIONS in the "Dragon Cave" at Mixniz, Styria, have been already noticed (NATURE, vol. xviii. p. 618). The diggings made in June, 1878, by the Anthropological Society of Gratz, have brought to light some bones bearing indistinct marks of cutting and percussion. Above the stalagmitic layer over the hearth-stuff some bones were found, in loam, well preserved, but probably derived from an older site. They are greenish, and partly of an intense bluish-green tint; and Prof. C. Doelter finds that their composition approaches that of turquoise [bone-turquoise?]. A full account by Prof. R. Hoernes will be found in the *Proc.* Imp. Geol. Instit. Vienna, August 31, 1878.

THE additions to the Zoological Society's Gardens during the past week include a Yellow Baboon (*Cynocephalus babouin*), from West Africa; two Ring-tailed Lemurs (*Lemur catta*), from Madagascar, presented by Mr. G. A. Shaw; a Green Monkey (*Cercopithecus callitrichus*), from West Africa, presented by Mr. J. Williams; a Common Fox (*Canis vulpes*), British, presented by Mr. Sntton Sharpe; a Woodcock (*Scolopax rusticola*), European, presented by Messrs. E. and W. H. Davis; a Common Swan (*Cygnus olor*), European, presented by Capt. Marx; a Ring-tailed Lemur (*Lemur catta*), from Madagascar, deposited; an Ocelot (*Felis pardalis*), from America; a Cereopsis Goose (*Cereopsis novæ-hollandiæ*), from Australia; three Yellow-winged Blue Creepers (*Cœreba cyanea*), from South America, purchased.

ON HELIOTROPISM IN PLANTS

THE heliotropic phenomena in plants form the subject of a monograph by Herr Wiesner, the first part of which has been recently communicated to the Vienna Academy. The following outline from the *Anzeiger* of the Academy will give an idea of some of the fruits of the author's researches on this important subject.

The first section treats of the history of the subject. In the second section the author studies the *influence of light* on heliotropism. The experiments were made in the light of a gas flame which burned under a constant pressure with a uniform intensity (luminous power = 6·5 spermaceti candles). The unit for the measurement of the light-intensity was the strength of this flame at the distance of one metre. It was found that in heliotropism three cardinal points of light-intensity are to be distinguished; an upper limit, a lower limit, and between the two an *optimum* of light intensity. Thus with decreasing intensity of light the strength of the heliotropic effect increases to a certain point, and beyond this point decreases. The lower limit referred to coincides with the lower limit of light-intensity for the stoppage of growth in length, while the upper limit does not coincide, or only occasionally coincides, with the upper limit of light-intensity for growth in length, for in th case of plants very sensitive heliotropically it lies higher, and in less sensitive plants lower, than the upper limit for growth in length. The mode of arrangement of the experiment in gas-light did not permit of determining in all cases the limiting values of the light-intensities; thus, for example, the upper limit for the heliotropism of etiolated shoots of *Salix alba*, and of the hypocotylous portion of the stem of *Viscum album*, and the lower limit for the heliotropism of the growing stem of vetch could not be ascertained. The former lies above 400, the latter far below 0·008. The optima were found to lie between 0·11 (the growing stem of the pea) and 6·25 (etiolated shoots of *Salix alba*). Both with gas-light and with natural light it was ascertained that beyond a certain intensity no growth in length occurs.

The third section treats of the relations between the *refrangibility* of the light rays, and the heliotropic effects. The experiments were made partly in the objective spectrum, partly in varieties of light, got by sending white light through coloured solutions. . . . It was proved that portions of plants very sensitive helictropically, *e.g.*, growing stems of *Vicia sativa*, undergo curvatures in all kinds of light, even in ultra-red and ultra-violet, with the exception of yellow. The maximum of the heliotropic force of light lies at the boundary between violet and ultra-violet; a second (smaller) in the ultra-red. From both maxima the power of the rays to produce heliotropism decreases gradually on to the yellow. Portions of plants little sensitive heliotropically, are no longer influenced by orange, or by red and green, or even (in the case of etiolated shoots of *Salix alba*) by ultra-red rays. The yellow rays quite stop the heliotropism, for, *e.g.*, in pure red a quicker and stronger heliotropism occurs than in a light which gives yellow besides red.

In the fourth section experiments are described on the joint action of (positive and negative) heliotropism and (positive and negative) geotropism. It is here shown, *inter alia*, that, in the case of plants very sensitive heliotropically, the geotropism is, at the optimum of light-intensity, apparently extinguished, even in strongly geotropic organs; further, that in many organs (growing stem of the pea), the heliotropic and geotropic powers of curvature disappear simultaneously; in others, however (stems of cress), the younger portions of the stem are more strongly heliotropic than the older, and the oldest after-growing portions of stem no longer show bendings in the light, but, through drawing action on one side (the heliotropic overhanging point of the stem), show apparently heliotropic curvatures chiefly due to growth, which are then counteracted by negative geotropism.

The arguments which go to prove that heliotropism is due to the phenomenon of unequal growth upon unequally-lit sides of an organ are set forth in the next section, and proof is offered that, for heliotropism as well as for growth in length, free oxygen is necessary.

The last chapter furnishes proof that the conditions for heliotropism remain constantly the same during its course, and coincide with the conditions for growth in length; further, that heliotropism (and the same holds good for geotropism) occurs as a phenomenon of induction. In this chapter it is also shown that when light induces heliotropism in an organ, a fresh heliotropic or geotropic induction meets with resistances, and can only come into action after extinction of action of the first; and that successive impulses of light and gravity, of which each by itself is capable of producing certain effects, do not have their actions added together when the effects that should be obtained separately are in the same direction, *e.g.*, one and the same side of the organ is helped in its growth in length.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 5.—"On a Machine for the Solution of Simultaneous Linear Equations," by Sir William Thomson. Let B_1, B_2, ... B_n be n bodies each supported on a fixed axis (in practice each is to be supported on knife-edges like the beam of a balance).

Let $P_{11}, P_{21}, P_{31}, \ldots P_n$ be n pulleys, each pivoted on B_1;
  $P_{12}, P_{22}, P_{32}, \ldots P_{n2}$,, ,, B_2;
  $P_{13}, P_{23}, P_{33}, \ldots P_{n3}$,, ,, B_3;
  ....
,, $C_1, C_2, C_3 \ldots C_n$, be n cords passing over the pulleys;
,, $D_1, P_{11}, P_{12}, P_{13}, \ldots P_{1n}, E_1$, be the course of C_1;
,, $D_2, P_{21}, P_{22}, P_{23}, \ldots P_{2n}, E_2$, ,, ,, C_2;
  ....
,, $D_1, E_1, D_2, E_2 \ldots D_n, E_n$, be fixed points;
,, $l_1, l, l_3, \ldots l_n$ be the lengths of the cords between D_1, E_1, and D_2, E_2, ... and D_n, and E_n, along the courses stated above, when B_1, B_2, ... B_n, are in particular positions which will be called their zero positions;

Let $l_1 + e_1, \ldots l_2 + e_2, \ldots l_n + e_n$ be their lengths between the same fixed points, when B_1, B_2, ... B_n are turned through angles $x_1, x_2, \ldots x_n$ from their zero positions;

(11), (12), (13), ... (1n),
(21), (22), (23), ... (2n),
(31), (32), (33), ... (3n),
....

quantities such that

$$\left.\begin{array}{l}(11)x_1 + (12)x_2 + \ldots + (1n)x_n = e_1\\ (21)x_1 + (22)x_2 + \ldots + (2n)x_n = e_2\\ (31)x_1 + (32)x_2 + \ldots + (3n)x_n = e_3\\ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\\ (n1)x_1 + (n2)x_2 + \ldots + (nn)x_n = e_n\end{array}\right\}\ldots\ldots\ldots\ldots\ldots(\mathrm{I}).$$

We shall suppose $x_1, x_2, \ldots x_n$ to be each so small that (11), (12), ... (21), &c., do not vary sensibly from the values which they have where $x_1, x_2, \ldots x_n$, are each infinitely small. In practice it will be convenient to so place the axes of $B_1, B_2, \ldots B_n$, and the mountings of the pulleys on $B_1, B_2, \ldots B_n$, and the fixed points D_1, E_1, D_2, &c., that when $x_1, x_2, \ldots x_n$ are infinitely small, the straight parts of each cord and the lines of infinitesimal motion of the centres of the pulleys round which it passes are all parallel. Then $\frac{1}{2}$ (11), $\frac{1}{2}$ (21), ... $\frac{1}{2}$ (n1) will be simply equal to the distances of the centres of the pulleys $P_{11}, P_{21}, \ldots P_{n1}$, from the axis of B_1;

$\frac{1}{2}$ (12), $\frac{1}{2}$ (22) ... $\frac{1}{2}$ (n2) the distances of $P_{12}, P_{22}, \ldots P_{n2}$ from the axis of B, and so on.

In practice the mountings of the pulleys are to be adjustable by proper geometrical slides, to allow any prescribed positive or negative value to be given to each of the quantities (11), (12), ... (21), &c.

Suppose this to be done, and each of the bodies B_1, B_2, ... B_n to be placed in its zero position and held there. Attach now the cords firmly to the fixed points $D_1, D_2, \ldots D_n$ respectively; and, passing them round their proper pulleys, bring them to the other fixed points $E_1, E_2, \ldots E_n$, and pass them through infinitely small smooth rings fixed at these points. Now hold the bodies $B_1, B_2, \ldots$ each fixed, and (in practice by weights hung on their ends, outside $E_1, E_2, \ldots E_n$) pull the cords through $E_1, E_2, \ldots E_n$ with any given tensions[1] T_1, T_2, T_n. Let $G_1, G_2, \ldots G_n$ be moments round the fixed axes of $B_1, B_2, \ldots B_n$ of the forces required to hold the bodies fixed when acted on by the cords thus stretched. The principle of "virtual velocities," just as it came from Lagrange (or the principle of "work"), gives immediately, in virtue of (I),

$$\left.\begin{array}{l}G_1 = (11)\ T_1 + (21)\ T_2 + \ldots + (n1)\ T_n\\ G_2 = (12)\ T_1 + (22)\ T_2 + \ldots + (n2)\ T_n\\ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\\ G_n = (1n)\ T_1 + (2n)\ T_2 + \ldots + (nn)\ T_n\end{array}\right\}\ldots\ldots\ldots(\mathrm{II}).$$

Apply and keep applied to each of the bodies, $B_1, B_2, \ldots B_n$ (in practice by the weights of the pulleys, and by counter-pulling springs), such forces as shall have for their moments the values $G_1, G_2, \ldots G_n$, calculated from equations (II) with whatever values seem desirable for the tensions $T_1, T_2, \ldots T_n$. (In practice, the straight parts of the cords are to be approximately vertical, and the bodies $B_1, B_2, \ldots, B_n$ are to be each balanced on its axis when the pulleys belonging to it are removed, and it is advisable to make the tensions each equal to half the weight of one of the pulleys with its adjustable frame.) The machine is now ready for use. To use it, pull the cords simultaneously or successively till lengths equal to $e_1, e_2, \ldots e_n$ are passed through the rings $E_1, E_2, \ldots E_n$, respectively.

The *pulls* required to do this may be positive or negative; in practice, they will be infinitesimal, downward or upward pressures applied by hand to the stretching weights which remain permanently hanging on the cords.

Observe the angles through which the bodies $B_1, B_2, \ldots B_n$ are turned by this given movement of the cords. These angles are the required values of the unknown $x_1, x_2, \ldots x_n$, satisfying the simultaneous equations (1).

The actual construction of a practically useful machine for calculating as many as eight or ten or more of unknowns from the same number of linear equations does not promise to be either difficult or over-elaborate. A fair approximation being found by a first application of the machine, a very moderate amount of straightforward arithmetical work (aided very advantageously by Crelle's multiplication tables) suffices to calculate the residual errors, and allow the machines (with the setting of the pulleys unchanged) to be re-applied to calculate the corrections (which may be treated decimally, for convenience): thus, 100 times the amount of the correction on each of the original unknowns, to be made the new unknowns, if the magnitudes thus falling to be dealt with are convenient for the machine. There is, of course, no limit to the accuracy thus obtainable by successive approximations. The exceeding easiness of each application of the machine promises well for its real usefulness, whether for cases in which a single application suffices, or for others in which the requisite accuracy is reached after two, three, or more of successive approximations.

[1] The idea of force here first introduced is not essential, indeed is not technically admissible to the purely kinematic and algebraic part of the subject proposed. But it is not merely an ideal kinematic construction of the algebraic problem that is intended; and the design of a kinematic machine, for success in practice, essentially involves dynamical considerations. In the present case some of the most important of the purely algebraic questions concerned are very interestingly illustrated by these dynamical considerations.

Mathematical Society, December 12.—Mr. C. W. Merrifield, F.R.S., president, in the chair.—Prof. W. S. Jevons, F.R.S., was elected a Member.—The following communications were made to the Society:—Mr. H. Perigol, on a kinematic paradox (the rotameter); Mr. S. Roberts, F.R.S., on the forms of numbers determined by continued fractions; Prince Camille de Polignac, on a graphic construction of the powers of a linear substitution.

Linnean Society, December 5.—Prof. Allman, F.R.S., president, in the chair.—Dr. I. Bayley Balfour demonstrated the peculiarities of a rare Myxomycetes, which species of Heterodictyum he showed bore characters intermediate between Cribraria and Dictydium.—Mr. G. Murray called attention to a peculiar greenish-yellow fungus (*Hygrophorus Wynniæ*, Berk. ?) from Bridlington, Yorkshire.—Examples of a moss new to Britain, the *Aulacomnion turgidum*, were shown by Mr. E. M. Holmes, who stated that they were found by Mr. West and Dr. F. Arnold Lees in Yorkshire; a comparison between the above and the common *A. palustre* was made.—Mr. F. H. Waterhouse read a paper on some Coleoptera collected by Charles Darwin, of geographical interest. These had lain undetermined for a long series of years, and now prove new to science. *Phytosus Darwinii*, from the Falklands, has unusually long, slender claws; *Choleva falklandica* is elliptical-shaped and strongly punctated. *Elmis brunnea* and *Anthicus Wollastoni*, from St. Helena, are noteworthy, inasmuch as Mr. Wollaston ("Coleop. St. Hel.") does not record either genus as existent there. *Scaphisoma elongatum*, from Rio de Janeiro, is the first species of the genus known to inhabit South America; and Prosthetops (*P. capensis*) is a novel genus with two ocelli, from South Africa.—Mr. C. B. Clarke, in a note on *Gardenia turgida*, stated that in books the flower calyx of males was alone described, while all herbaria specimens are diœcious, and males and females have hitherto been referred to different genera. The precise characters of each were denoted.—Dr. F. Day gave a summary of his (third) concluding paper on the geographical distribution of the Indian fresh-water fishes, in this dealing with the families Scombresocidæ, Cypriodontidæ, Cyprinidæ, Notopteridæ, and Symbranchidæ. Among the eighty-seven genera two only are African, thirty-two extend to the Malay Archipelago, and twelve are common to Africa and Malaya; of 369 species two are African, twenty-seven Malayan, and two common to both regions. In short, the fresh-water fish affinities preponderate to the Indo-Chinese and Malayan sub-regions; thus supporting Mr. Wallace's opinion as opposed to the view held by Mr. Blandford, who gives greater weight to African relationships, at least so far as mammals are concerned. Dr. Day, moreover, contends that the Indian fresh-water fishes point to three subordinate separate faunas—1. That belonging to the Ghauts, Ceylon, the Himalayas, and Malay Archipelago; wherein may be distinguished two fish races, a Palæarctic and a Malayan. 2. A fauna of the plains west of the Indus, with an African element in it. 3. That (by far the largest) spread over the plains east of the Indus, and which appears to have a Burmese connection.—The abstract was read of a second contribution on the mollusca of the *Challenger* Expedition, by the Rev. R. Boog Watson. This consisted of descriptions of species of Trochidæ belonging to four genera, viz., *Sequinzia*, *Basilissa*, *Gaza*, and *Bembix*; the three last being new and otherwise remarkable.—Messrs. Dowdeswell, Arthur Hammond, Thos. Hanbury, Joseph Sidebotham, Wm. Thomson, and Chas. A. Wright were elected Fellows of the Society.

Zoological Society, December 3.—Mr. Robert Hudson, F.R.S., vice-president, in the chair.—Mr. H. Seebohm, F.Z.S., exhibited a series of specimens of the hooded and carrion crows, and made remarks on their intermediate forms and geographical distribution.—Col. L. H. Loyd Irby, F.Z.S., exhibited and made remarks on the nests, eggs, and young of *Cypselus pallidus*, taken at Gibraltar.—Mr. Howard Saunders, F.Z.S., exhibited and made remarks on some eggs of Indian Laridæ (*Sterna bergii* and *Larus hemprichii*), which had been taken by

Capt. Butler, of H.M.'s 83rd Regt., on the Mekran Coast.—Dr. Day, F.Z.S., exhibited and made some remarks on some jaws of Indian sharks belonging to the genera *Galeocerdo* and *Carcarias.* —The Secretary called attention to an error which had been made in reference to the collection of butterflies from Billiton, reported on by Messrs. Godman, Salvin, and Druce, in the last part of the Society's *Proceedings*. The collection had been made and forwarded to England by Herr J. G. F. Riedel, of Koepang. —Mr. Sclater communicated some further particulars respecting the occurrence in Lancashire of the specimen of the black-throated Wheatear (*Saxicola stapazina*) exhibited at the last meeting of the Society.—Prof. A. H. Garrod, F.R.S., read a paper on the conformation of the thoracic extremity of the trachea in the birds of the order Gallinæ.—A communication was read from Dr. A. Günther, F.R.S., containing the description of some reptiles from Midian, collected by Major Burton. Amongst these were two new snakes proposed to be called *Echis decorata* and *Zamenis elegantissima*.—Mr. H. Seebohm pointed out the character of a new Sylvia from Abyssinia, proposed to be called *Sylvia blanfordi*, after Mr. Blanford, by whom it was obtained during the Abyssinian Expedition.—Mr. H. Seebohm also read notes on the identity of the birds which had been named *Hororni fortipes*, *Neornis assimilis*, *Horeites robustipes*, *H. brunneus* and *H. pallidus*, and proposed to reduce them to one species under the name *Cettia fortipes*.—Mr. Martin Jacoby read descriptions of some new species of Phytophagous Coleoptera from Central and South America.

Anthropological Institute, November 26.—Mr. John Evans, F.R.S., president, in the chair.—The Rev. John Robbins, D.D., was announced as a Member.—Mr. Worthington G. Smith exhibited a series of flint implements from the valley of the River Lea.—Mr. A. L. Lewis read a paper on the evils arising from the use of historical national names as scientific terms. The propositions which he endeavoured to establish were: 1. That there were at the first population of Europe certain primitive races, of which three are particularly described. 2. That these races are so mixed that at the present day the representatives of them appear not only in most European nations, but in the same families and among children of the same parents. 3. That notwithstanding this mixture and the effects which it must permanently have, racial characters display an astonishing permanence. 4. That this mixture, being so slow in its effects and yet having become so general, has probably been at work for a very great length of time—so great that the peoples to whom the earliest history introduces us were probably nearly as much mixed as those of the present day. 5. That it is desirable to discontinue the use of political names of those peoples as ethnic names, and to employ others, based on the physical characteristics of the individual. 6. That while physical characteristics are the only basis for a true division into races, yet in the practical application of this division the influence upon individuals of different races of a community of language, custom, history, or tradition must not be lost sight of, although these things do not prove community of race, but only the contact at some time or other of the races to whom they are now common.—The director read a paper by Prof. Daniel Wilson, LL.D., on some American illustrations of the evolution of new varieties of men. In the mingling of different races in America, so complex and varied, all subjected to the influences of climate and social habits, and all mingling in blood in a greater or less degree with the native red races, hybridity had resulted on a great scale. The process had already been developed sufficiently long to afford important indications of the evolutions of permanent hybrid varieties. A specimen is to be seen among the tribes of the half-breeds in Manitoba, as it were in the process of evolution; while sheltered within the remote Arctic regions man can be studied among the Esquimaux in conditions closely analogous to those which are ascribed to a post-pliocene, if not to a pre-glacial period. In the abrupt collision of the civilised races of Europe with the American aborigines, it had always been taken for granted that the latter were doomed to inevitable extinction, and that the land would be peopled with the purely civilised races of the world. There is no question, however, that from an early date there have been intermarriages between Europeans and the American races. A growing feeling is manifesting itself in the United States and Canada that the Indian population is not doomed to extinction, and that a much larger amount of healthy intermarrying and consequent absorption has existed than unobserving critics had any conception of, and the native Indian element is a factor in the population of the New World destined to exercise an enduring influence on the ethnical character of the Euro-American races.

CAMBRIDGE

Philosophical Society, November 4.—The following communications were made to the Society:—The physical constants of hydrogenium, by Prof. Dewar, Part 2. This paper is a continuation of an investigation into the physical constants of hydrogenium. The first part appeared in the *Transactions* of the Royal Society of Edinburgh, vol. xxvii., and had reference to the specific gravity, specific heat, and coefficient of expansion of the occluded hydrogen. These observations led to the conclusion that the specific gravity was independent of the amount of condensed gas, and had a mean value of 0·62. This result has been confirmed by the subsequent experiments of Troost and Hautefeuille, and what is very remarkable, they deduce an identical value for the density of hydrogen from observations on the hydrides of potassium and sodium. The specific heat, relatively to palladium, of the condensed hydrogen, appeared to vary inversely as the charge, but taken relatively to successive charges was nearly constant, and had the value 3·4, which is identical with that of gaseous hydrogen at constant pressure. The coefficient of the cubical expansion of the alloy is about twice that of palladium, and that of the hydrogen in its compressed state not more than three times that of mercury. This communication deals with the thermo-electric relations and conductivity of hydrogenium. It is shown that the electro-motive force of a junction of hydrogenium palladium is at ordinary temperatures nearly equal to that of an iron copper junction, and that it increases with the temperature according to the general parabolic law, the rate of the increase being, however, greater than iron copper and subject to a regular variation on account of successive heatings. The formation of thermo-electric piles, and of neutral points in a uniform wire of this substance, along with the continuous formation of thermo-electric currents through the application of a hydrogen flame were explained and shown. Experiments on the electric resistance show that it increases directly as the amount of condensed gas.—Studies in spectrum analysis, by Professors Liveing and Dewar. The authors describe the reversal of characteristic lines of rubidium and cæsium when the chlorides are heated with sodium in glass tubes in an atmosphere of hydrogen or nitrogen, and a bright light is viewed through the vapours. They remark that the violet lines of rubidium, and the most refrangible of the cæsium lines are first seen, and broaden out the most when the temperature rises, contrary to what might have been expected from the analogy of other cases. The absorption lines observed coincided with the bright lines of the metals heated in a flame, not with the lines which they give in a dense electric spark; but the authors obtained spectra similar to the flame spectra by passing sparks from an induction coil without a Leyden jar, between beads of fused chlorides of those metals, although simpler spectra were produced by the more abrupt discharges produced by interposing a Leyden jar. The authors further described absorption spectra produced by magnesium vapour when mixed with hydrogen, potassium, and sodium respectively. That produced by magnesium and hydrogen consisted of a line a little less refrangible than the *b* group, and a band rather more refrangible than the *b* group, fading away towards the blue. The constant appearance of these absorptions when the vapour of magnesium in hydrogen was observed in a hot iron tube, led to the endeavour to obtain the corresponding luminous spectrum. This they succeeded in doing by taking sparks from an induction coil, without a Leyden jar between magnesium wires in a tube full of hydrogen. It appears that the compound to which this spectrum is due is formed only within a certain range of temperature, and is dissociated at higher temperatures—for the spectrum is scarcely seen at all when a large Leyden jar is used, which may be supposed to have the effect of shortening the time of discharge and increasing the temperature. Further, this compound does not seem to be formed when the pressure of the hydrogen is much reduced. In the case of sodium and magnesium they observed an absorption line in the green not observed in either vapour separately; and when potassium and magnesium were used, a characteristic pair of lines in the red always appeared, and sometimes another line in the blue. The authors have not yet seen these as bright lines. In the course of observations on the spectra of sundry rarefied gases the authors have been led to conclude that electric sparks take a selective course in a mixture of gases, and that the differences in the spectra

observed in different parts of the same tube are probably due to the existence of more than one gas in the tube. Tubes of nitrogen which did not show the lines of hydrogen at all when sparks from an induction coil without a Leyden jar were passed through them, gave strong hydrogen lines when a large jar was interposed. A bulb tube with magnesium wires filled with hydrogen at low pressure gave in one half scarcely any spectrum but the F-line of hydrogen, while the other half gave the spectrum of acetylene. They generally found hydrogen lines and flashes of sodium (no doubt from the glass) in tubes very much exhausted; and they conclude that impurities enter such tubes from sources hitherto unsuspected. Tubes filled with oxygen obtained from silver iodate have been found to give the spectrum of iodine, pointing to the conclusion that chemical reactions occur at very low pressures which are not produced under other circumstances. Generally the authors conclude that the spectrum of a gas in a rarefied state affords the most delicate test of its purity, and that it is to the chemical problem of obtaining pure gases that attention needs to be specially directed.

PARIS

Academy of Sciences, December 9.—M. Fizeau in the chair.—The following papers were read:—New method for determining the flexion of telescopes, by M. Loewy. The principle is to produce in the field, besides the images of the eyepiece and objective (whose position may vary), a third image emanating from the axis of rotation, which, completely independent of the flexion of the tubes, undergoes only a slight displacement due to the auxiliary lens. This image serves as a means of estimating the relative displacement of the two others. (A concavo-convex lens is placed in the axis of the central cube, and on its axis of rotation.)—Examples of calculation of the torsion of prisms with mixtilinear base, by M. de Saint-Venant.—On the binary form of the seventh order, by Prof. Sylvester.—Study on ordinary and compound steam engines, steam jackets, and superheating, according to experimental thermodynamics, (extract), by M. Ledieu. Some observations are here made on neutral spaces and their influence, the restriction of these having been one direction of recent improvement.—On the works of the Saint Gothard tunnel, by M. Colladon. After recounting obstacles which have retarded the work—among others, greatly increased and violent infiltration, and the swelling of a plastic mass of decomposed felspar and gypsum on contact with moist air, exerting tremendous pressure on supports—he gives information about the air compressing and ventilating apparatus and the boring machines. It is expected that about eight years wlll suffice for the completion of the work. The difference between the first estimated and actual expense will, it is thought, be nearly 100 million francs.—On a series of soundings undertaken by M. Roudaire in view of the formation of the African interior sea, by M. De Lesseps. These soundings will cover about 500 leagues, and will occupy M. Roudaire about six months, after which it will be possible to estimate fairly the expense of the project. M. De Lesseps describes what he saw of that region.—Report on a memoir of Prof. Lawrence Smith on the native iron of Greenland and the dolerite it contains. The reporters recommend insertion of this interesting memoir in the *Recueil des Savants étrangers*.—Diseases of plants caused by *Peronospora*; attempted treatment; application to the lettuce-disease, *P. Gangliiformis*, Berk. Memoir by M. Cornu.—M. Werdermann replied to M. Reynier's reclamation of priority with regard to the electric lamp. He maintains that his (W.'s) lamp depends not on the effect of incandescence of a heated carbon, but on an extremely small voltaic arc; the incandescence of a small part of the electrode is merely an inevitable consequence.—On an automatic regulator of currents, by M. Hospitalier. This consists of a one-layer resistance bobbin, having a portion of its wire laid bare, and in contact with a slightly convex distributor connected with an armature before an electro-magnet which is affected by the current to be regulated.—On a small telephonic apparatus, by M. Boudet de Paris (sealed packet opened). This refers to a telephone in the form of a watch, which, with a microphone, gives speech well. M. du Moncel referred to a very advantageous arrangement of a speaking microphone (by M. Boudet de Paris), which he would shortly describe.—On the reduction, in continuous fractions, of a pretty extensive class of functions, by M. Laguerre.—On a point in the history of mathematics, by M. Desbovas.—Theorems on prime numbers, by M. Proth.—On a remarkable specimen of siliciuret of iron, by Prof. Lawrence Smith. This piece is remarkably rich in silicium (about 15 per cent.), and is evidently the product of a blast furnace. There are no such furnaces where it was found, but there are some a few miles away, and about 100 miles from the spot was one which supplied iron having 8 per cent. silicium, and gave up working because of want of demand for such iron. Prof. Smith thinks the piece may have been (exceptionally) produced there. M. Daubrée said industry has never been known to produce an alloy of iron with nearly so much silicium. The highest proportion at the Exhibition was 10 per cent.—On a new acid obtained from camphor, by M. Haller.—On the formation of hexamethylbenzine by the decomposition of acetone, by Mr. Greene.—On normal ethyloxybutyric acid and its derivatives, by M. Duvillier.—On the presence of ytterbine in the sipylite of Amherst, by M. Delafontaine.—Existence of baryta and strontian in all rocks constituting primordial strata; metalliferous veins with gangue of baryta, by M. Dieulafait. He infers from the facts that baryta and strontian have the same origin, viz., the primordial rocks; hence the metalliferous ores (manganese, lead, zinc, &c.), for which baryta serves as gangue, has also this origin.—On the dangers in use of borax for preservation of meat and the reasons why some substances cause meat to lose its nutritive properties, by M. Le Bon. He prescribes, in principle, the use of chemical substances, even the apparently inoffensive salt, for preservation of meat. The most nutritive part of meat is the juice, and this, when the meat is put in saline solution or covered with a salt in powder, makes rapid exchange of its nutritive principles through endosmose. He hints at a new mode of preservation, however, other than cold.—On an artificial pyroxene (diopside), by M. Gruner.—Influence of atmospheric electricity on fructificatien of plants, by M. Grandeau. It greatly stimulates the phenomenon.—On a disease of the coffee-tree observed in Brazil, by M. Jobert.—On the diffusion of heat by leaves, by M. Maguenne.—On the power of absorption of water by wood, by M. Maumené. The property varies (for different woods) between 9·37 and 174·88 per cent. of the absolutely dry wood; the latter figure was obtained with chestnut.—On a scientific balloon ascent of October 31, by M. Tridon.

CONTENTS

THURSDAY, DECEMBER 26, 1878

THE ASSOCIATION OF LOCAL SOCIETIES

LOCAL Societies: What is their aim and what purpose do they serve? How may this aim be most surely gained? How can this purpose be most effectively carried out? These are questions which naturally arise when considering the subject of local societies.

The *aim* of every local society should be to raise the intellectual status of the locality. The *purpose* to do so in that way most generally useful. It is the mind of the community which has to be raised by affecting the minds of the individuals. Individual minds are to be affected by contact with material surroundings. These surroundings influence us through the powers of observation, hence *careful and accurate observation* must exist among the members of a society fulfilling its proper functions. The greater the number of members exercising such observation the greater the usefulness of the society. It is almost needless to instance other mental qualities as necessary for success, because experience shows that when once the observing faculty has received its due share of attention, the power of using the observations made follows in due course. The faculty of observation must be drawn out and cultivated by contact with matter in relation to man, and by contact with matter considered apart from man as existing in a state of nature. And just as it is important that in the culture of the individual a one-sidedness should be specially avoided, so in raising the culture of a community it is equally important that opportunities or suggestions for mental improvement *all round* should be afforded. Hence we are inclined to think it advisable that especially in the case of small country towns scientific studies, or suggestions for such, should proceed from the same platform as those studies which are often spoken of as more purely literary. Of course *literature* includes the records of science, but still for general purposes the meaning is clear when a literary institute or society is spoken of as distinguished from a scientific. Among the lower types of animals there is a want of specialisation of parts; very different functions may be performed by the same part or the whole of the body; in the higher, specialisation prevails, each function has its own organ, and the function is performed more efficiently. In large towns science may be pursued apart from general literature, and even each special science may stand on its own platform, but in small towns this is out of the question, and I believe unadvisable, for the over-performance of one function in the lowly organised society s checked by the claim of the general body. Moreover, the tastes of a community being naturally various, it becomes essential to present intellectual food of various kinds. Hence we cannot but think that small local societies should be both literary and scientific. The two aspects of culture will support and strengthen each other, and the introduction of a new clique, or party, or sect be avoided. For it must be remembered that one of the distinct collateral advantages of such societies is that a common platform is provided upon which men of all political or religious beliefs can stand and work together. No one who is acquainted with the social conditions of our small towns can underrate the importance of this.

But how are such societies to work? I would reply, from within, outwards. Not, in the first place, by calling in extraneous help, by engaging eminent men to give courses of lectures, but by arousing the spirit of inquiry and observation amongst the townsfolk. Let but a few natives come forward with short papers on any subjects with which they may be especially acquainted, the subjects being treated in such a way as to elicit a discussion or inquiries, a spirit of interest will soon be aroused, and minds put into a proper attitude for the reception of truths before quite unknown to them, and for the prosecution of some special subject as a study. In practice I would strongly advise the following course to be pursued by any embryo literary and scientific society. Have two classes of meetings: one the *ordinary meeting*, at which members alone (and therefore townsfolk) should read short papers, upon which a discussion should afterwards be encouraged; and *public lectures*, given mainly by non-residents, and to which the general public should be admitted on the payment of a small fee. At the ordinary meeting the local talent and observation is drawn out, and at the public lecture new subjects are introduced to the notice of members. At the former, notices of local phenomena and history, or the occasional original investigations of members, are recorded; at the latter, new lines of thought are often indicated, or systematic instruction given in some one subject.

A society established on some such basis is then in a position to encourage the collection of objects of *local* natural history, to establish a *local* museum, and carry out field excursions during the summer months. Moreover, the experience of many years past has shown me that the life—and therefore the growth of culture—in such a society is far greater than in those cases where only a yearly course of *lectures* is organised, the greater part of them being given by strangers. Next comes the oft-repeated question, But how long will such a society last? Many are ready to say, We have tried some such plan, and success has attended our efforts for one or two years, and then the society has died out. On this part of the subject a few words will now be said, and the remarks made are founded upon experience gleaned amidst the practical working of local societies in Cumberland during the past nine years.

How, then, can permanence be ensured? In a small town or district local resources and talent are apt to become exhausted or unavailable. A time will surely come when the intellectual movement will wane and the society be on the brink of non-existence. But the very usefulness of such a movement must consist in its stability; there should be a growth, not a bare existence. To insure this stability I suggested some years ago that the four societies then existing in the Lake District and West Cumberland should be united for general purposes, while each society should retain its individuality. After many preliminary difficulties were overcome, the union was effected, and since that time each society has grown stronger, four new societies have been formed, and the total number of members increased from a few hundred to nearly 1,200.

The objects to be attained by this association of societies are as follows:—1. Increased strength to be derived from mutual help, encouragement, and a spirit of

honest emulation. 2. The union affords greater facilities towards publishing transactions and securing the services of eminent lecturers. 3. An annual meeting of the associated societies affords an opportunity for the discussion of principles of working and promotes the general life. 4. The annual meeting being held in a fresh town each year helps to keep the country alive to the Association work, and encourages the formation of new societies.

The constitution of the Cumberland Association is as follows:—The president to be a man of local note and high culture, and to serve for a period not greater than two years.[1] The Presidents of individual societies to be vice-presidents of the Association. The council of the Association to consist of two delegates from each society, chosen annually. The treasurer and secretary (honorary) to be one and the same person, and fully acquainted with the county in all its aspects.

The working of the Association is carried on thus: The Association secretary keeps a record of all papers and lectures brought before the individual societies. Before the commencement of each winter session he communicates with all the local secretaries, and from his knowledge of available intellectual stores in the county, helps each in the drawing up of the winter programme in whatever direction help may be specially needed. It is his duty also to help forward the establishment of local classes where such are possible. At a council meeting held in the autumn some public lecturer is decided upon who shall go the round of the associated societies during the winter, and a grant is made towards his expenses from the Association funds (of which more anon), the rest being made up by each society served.

The annual meeting takes place at Easter or in May, and lasts two or three days. The Association President delivers his annual address, reports from the several societies are read and discussed, original papers are read, lectures given by one or more eminent men, and field excursions made.

At the close of each winter session the local secretaries send into the Association secretary any papers which have been selected by the local committees as worthy of publication. If the Association council approve these papers they are published in the *Transactions* at the Association expense. The funds of the Association are gathered thus: Each society pays an annual capitation grant of 6*d*. per head on all its members. There is also a class of Association members, residing at a distance from, and not belonging to, any local society, who pay an annual subscription of 5*s*., and are virtually considered members of all the societies, and have the privileges of such. The *Transactions* are sold to the societies and Association members at the price of 1*s*., the public being charged 2*s*. 6*d*. Some of the societies purchase copies to the full number of their members, and present them, others take only a limited number of copies (determined by the local society committee) and re-sell to those of their members who care to possess them. In this way the greater part of an edition of 800 copies of the *Annual Transactions* is disposed of. Authors are allowed extra copies of their own papers at a moderate charge, and when all expenses are met, a fair balance is left to carry on to the next year.

It should be noted that of the eight societies in Cumberland, now associated, the local annual subscriptions of members in each society is generally 5*s*.; in one case, however, it is 3*s*. 6*d*., and in another 2*s*. 6*d*. It is a rule of the Association that members going from one society to another to afford help in the carrying out of the various programmes, should have their expenses paid by the society helped. Such is the general constitution and mode of working of the Cumberland Association, which has undoubtedly succeeded in its aim, so far as the keeping up of existing societies and the formation of new ones is concerned. The *Annual Transactions*, too, include many papers of local value, and some of general interest, while among the eminent men who have kindly come forward to lend their services at the Annual Meetings, are the Astronomer-Royal, the Bishop of Carlisle, Prof. Shairp, Prof. Wm. Knight, and I. Fletcher, M.P., F.R.S. At present, however, the Association is but in its infancy, and may be considered more or less of an experiment, yet that some such method of union is desirable amongst local societies in the various counties or districts of England few will deny. Time will show how the system may be improved and varied to suit special circumstances, but I cannot but think that the plan of association to carry out the larger objects of societies, and the annual meeting of the associated societies in successive towns of a county, must economise labour and promote the healthy culture of the county in which the work is carried on.

Amongst the difficulties presenting themselves in the early days of the association, the following occurred. For several previous years a Cumberland and Westmoreland Antiquarian and Archæological Society had flourished, and it was feared that the new County Association would clash with its existence. The Antiquarians thought it best not to amalgamate with the associated society, its constitution being in many points different from theirs, but it was resolved that whenever papers, bearing on local antiquarian or archæological subjects were read before any of the associated societies, these papers should be offered by the Association council to the Antiquarian and Archæological Society for publication in their *Transactions* if deemed worthy. Moreover, some of the officers of the Association are active members of the Archæological Society, and so far from their being any antagonism, the two decidedly help one another forward in the general work of gleaning local knowledge and diffusing culture.

As hon. secretary of the Cumberland Association, I should feel very grateful for any hints or suggestions from the readers of NATURE. What is wanted in every county is more culture, and that carried on in a *natural* way, and with a true love of nature in all her aspects.

J. CLIFTON WARD

[1] The Lord Bishop of Carlisle acted as president for two years, and I. Fletcher, M.P., F.R.S., is now in his second year of presidency.

NEWCOMB'S LUNAR RESEARCHES

Researches on the Motion of the Moon, made at the United States Naval Observatory, Washington. By Simon Newcomb, Professor U.S. Navy. Part I. (Washington, 1878.)

THE author prefaces his work with the remark that for several years after the publication of Hansen's Tables of the Moon, there was a very general belief that

the motion of our satellite could be followed by their means with the same accuracy as that of the other heavenly bodies, after having been made the subject of astronomical and mathematical research for two thousand years. This expectation was soon proved to be far from borne out. Prof. Newcomb showed in 1870 that the accuracy of the Tables since 1750 had been secured only by sacrificing the agreement with observations previous to that epoch, and that about 1700 the Tables deviated more widely from the observations than the previous ones; and it may be added that those who had been engaged in examining the old eclipses were aware that Hansen's Tables did not represent the phenomena only as far back as the commencement of the eighteenth century, so well as Burckhardt's or Damoiseau's, which had been used for our ephemerides up to the date of their publication.

A new investigation of the subject for the purpose, if possible, of ascertaining the cause of these unexpected deviations was entered upon at the Naval Observatory, Washington, and was made a part of our author's official duties in that establishment. In the present volume we have the results of researches on the discordances in question, based upon observations before the year 1750. This portion of the work was originally intended to follow the study of the mathematical theory of the inequalities of long period in the moon's mean motion, but for reasons explained in the Introduction, that part of the inquiry is still incomplete. The year 1750 was fixed upon as the terminal point in the investigation in this first part, as it is the epoch when exact meridian observations commenced, and that which separates the period within which we are in possession of observations reduced on modern data, from the period during which neither really accessible observations nor tables of reduction are available.

Prof. Newcomb supplies an historical introduction in which the discovery of the secular acceleration, and the examinations of ancient eclipses with the view to fix its correct amount by observation are briefly noticed, as also Ferrel's paper, published in 1853, containing "the first known attempt to calculate from theory the retardation produced by the action of the moon upon the tidal wave," and the researches of Adams and Delaunay. He proceeds to give a summary of the data now at our disposal for determining the apparent secular acceleration of the moon from observation alone. These include the statements of ancient authors from which it has been inferred that total solar eclipses have been witnessed at certain points of the earth's surface at dates approximately indicated, and the author points out the uncertainty attending our interpretation of such records. He considers that the circumstance which we should regard as most unequivocally marking the totality of an eclipse is the visibility of stars, though he thinks that even this criterion is hardly to be admitted as conclusive, because Venus may be seen during a considerable partial or an annular eclipse, and at certain times when there is no eclipse at all, there is also another difficulty in some cases, in determining the precise localities where the phenomena were observed. We have also the series of lunar eclipses upon which Ptolemy founded his theory and which are recorded by him in the Almagest. These are followed by the observations of the Arabian astronomers, chiefly contained in an Arabic manuscript belonging to the University of Leyden, a translation of which was made by Caussin and published by the French Government in 1804, under the title "Le Livre de la Grande Table Hakémite." Prof. Newcomb remarks that this work contains what are entitled to be considered the earliest astronomical observations of eclipses which have reached us, for although some of the data furnished by Ptolemy, Theon, Albategnius, and others, may have been the results of astronomical observations, in no case have the quantities actually observed been handed down to us. The entire number of eclipses in this collection is twenty-eight, and the times of concluded beginning and ending were usually determined by noting the altitudes, which were recorded sometimes in whole degrees only, at others "in coarse fractions of a degree." There must remain a doubt how nearly such times apply to those of actual contact, but Prof. Newcomb suggests in this part of his work that by the mean of all the observed times the error in the moon's mean longitude can be reduced to not more than a minute of arc. The Arabian observations are followed by those of European observers prior to the invention of the telescope, including Regiomontanus, Bernard Walther, and Tycho Brahe: of the latter, the author remarks, "It is wonderful if so indefatigable an observer never observed an occultation of a star or planet by the moon, yet I have never succeeded in finding any such;" he made a careful examination of Tycho's observations during periods in which the bright star Aldebaran must have been occulted, to no purpose. The observation of eclipses and occultations with the aid of a telescope, Prof. Newcomb remarks, may be considered as commencing with Bullialdus and Gassendus, but they had no clock, and only fixed the time by noting the altitude of the sun or a star. The application of the clock commences with Hevelius, and in the scarce volume of his "Machina Cœlestis" are found a number of occultations thus observed. Then follow the observations of Flamsteed and the astronomers at the observatory of Paris, the Cassinis, La Hire, and Delisle, the latter of whom also observed at St. Petersburg. Prof. Newcomb, during a visit to Paris, while Delaunay was in charge of the Observatory, was fortunate in having all the archives of that establishment unreservedly placed at his disposal. He found amongst them most of the original note-books of the French observers since the year 1675, in which were contained a great number of occultations that had been quite forgotten, those which had appeared in the *Memoirs* of the Academy, forming but a small fraction of the whole. Again, on visiting Pulkowa, M. Struve gave him access to the records of Delisle's observations, 1727 to 1747, forming a useful supplement to those of Paris, which had diminished in number after 1720.

Prof. Newcomb concludes this historical notice with remarks on observations since the time of Bradley, and granting certain fundamental premises, suggests that the secular acceleration of the moon may admit of nearly as accurate determination from the modern observations, as from their combination with the ancient ones.

Having thus briefly recapitulated the data available for investigation, the author adverts to ancient eclipses, presumed to have been total from the narrative of the historians, at certain points of the earth's surface. The

eclipses he admits in this category are eight in number, from that of Thales, B.C. 585, to the eclipse of A.D. 364, described as total at Eoos. Looking for mention of distinct indications of totality, he has not included such an eclipse as that of B.C. 763, the record of which was discovered by Sir Henry Rawlinson on one of the Nineveh Tablets in the British Museum, where importance appears to be attached to it by the description being underlined; hence its presumed totality. The eclipses of the moon recorded by Ptolemy in the Almagest are thoroughly examined, with satisfactory results, except in the case of the eclipse of B.C. 383, December 22, where there appears to be a mistake as to its having been really observed at Babylon; and he concludes that during the eight centuries preceding the Christian era the mean longitude of the moon in Hansen's Tables requires a correction of about 18′. The Arabian eclipses, solar and lunar, twenty-five in number, between A.D. 829 and 1004 are then compared with the Tables.

In the next two sections Prof. Newcomb supplies a full description of the method adopted for deducing the errors of the lunar elements from the eclipses and occultations, and for determining the effect of changes in the elements upon the path of the central line of an eclipse, adopting, in the latter case, formulæ originally given by Bessel.

In a following portion of the volume, occupying about a hundred pages, are given, mostly as originally recorded, the observations of occultations and eclipses by Bullialdus and Gassendus, Hevelius, and, as the author terms them, the astronomers of the French School, between 1670 and 1750, preserved in the archives at the observatories of Paris and Pulkowa; it is needless to say that this section possesses a great value, supplying as it does the particulars of so many observations hitherto unpublished. We have then the positions of the moon from Hansen's Tables, used in the comparison of the preceding observations with theory, in the calculation of which, and for the numerical work generally, Prof. Newcomb was assisted by a grant from Congress, sufficient to enable him to employ two computers. Certain modifications of the strict form of application of the Tables were considered allowable for the older observations, their degree of accuracy rendering an exact computation of Hansen s Fundamental Argument of no advantage, and he considers such modified plan of employing Hansen's Tables, preferable to the use of the older Tables, which might be adopted for the sake of saving labour. A "Tabular exhibit of Reduction of the Occultations," 286 counting immersions and emersions separately, is then given. The equations of condition for the occultations, and a provisional solution follow.

In the next section the author presents an elaborate discussion of eclipses from 1620 to 1715, which it may be remembered is the last total eclipse that was methodically observed in this country. In this series is included the eclipse of 1639, June 1, observed by Gascoigne and Horrox amongst others, and 1706, May 11, which was total in the south of France, but of which Prof. Newcomb takes no other observations into account than those of La Hire, of Paris: the fact, indeed, is that the observations along the belt of totality appear to be strangely and unaccountably discordant, so far at least as regards the beginning and ending of the total phase. The eclipse of 1715 is very fully discussed, and remarking that by Halley's organisation of a numerous body of observers throughout the path of the moon's shadow across England, valuable observations for determining its limits were procured, the author deduces from them a correction to the motion of the moon's node, which he finds to be $10'' \times T$ (T being counted in centuries from 1850), the argument of latitude being diminished by this amount; this result he considers nearly certain with respect to its algebraical sign, but observes that it must be affected by any corrections of Hansen's value of the moon's parallax.

We now reach the main conclusions to which Prof. Newcomb is led, by the laborious and masterly discussion of observations prior to 1750, of which necessarily little beyond an outline has been given here. The theoretical value of the secular acceleration of the moon's mean motion due to the cause discovered by Laplace, has been fixed with accuracy by Prof. Adams and Delaunay: the latter geometer, carrying his approximation to a greater number of terms than had been included by Prof. Adams, assigned $6''\cdot18 . T^2$. But this value, as is well known, has not been found to accord with the older observations, and the difference between the theoretical value and that which observation seemed to require, has been generally attributed to a retardation of the earth's axial rotation; thus, as Prof. Newcomb remarks, "the apparent secular acceleration will be made up of two parts—the one a real acceleration, the other an apparent one, due to the change in our measure of time. But further, he says it will be found that the hypothesis of a constant tidal retardation does not account for the observed mean motion of the moon, and either the retardation must be supposed variable, even to becoming at times an acceleration, or it must be admitted that her mean motion is affected by changes not hitherto explained. He then proceeds to inquire what deviations of the moon's mean motion remain unaccounted for, and with this object he first collects into tabular form the individual corrections to Hansen's mean longitudes, derived from the discussion of eclipses and occultations from 1621 to 1728, with their probable errors, the latter being necessarily somewhat arbitrary, for want of data for their rigorous computation. The older results do not exhibit larger discordances than might be expected. In order to complete the investigation of anomalies in the moon's mean motion unexplained, it was necessary to have the errors of Hansen's Tables from 1750 to the present epoch, or to 1875, and these were partly obtained from Hansen's paper in the *Monthly Notices* of the Royal Astronomical Society, and, since 1850, from Part III. of the publications of the American Transit of Venus Commission, where it was shown by Prof. Newcomb that at the epoch 1875·0 the meridian observations at Greenwich and Washington agreed in indicating a correction to the tabular mean longitude of $-9''\cdot7$. The occultations about the same time giving a correction nearly two seconds less, it is assumed that the true correction at this epoch was $-8''$. Hansen introduced in his tables a term depending on the argument, 8 times the mean motion of Venus *minus* 13 times the mean motion of the earth, which has not been theoretically explained, and is to be regarded as empirical. This term is therefore removed from the theory, before examining, as Prof. Newcomb proceeds to

do, how nearly theory alone, without any empirical correction, will represent the observations. It is then at once apparent that the residuals cannot be represented by corrections to the epoch of mean longitude, mean motion, and secular acceleration, and any approximation to a mean value of the latter would have different values, according to the mode of using the data. To obtain the best result from the ancient and modern observations combined, it was deemed advisable to assign a minimum probable error of 4″ or 5″ to each residual for the modern observations. Equations of condition for correction of epoch, mean motion and acceleration are formed, and extend from B.C. 688 to A.D. 1875, or over a period of 2,500 years, and the resulting corrections to Hansen's values for 1800, are, for mean longitude, $+3''\cdot90$, mean motion $-19''\cdot03$, and for secular acceleration $-3''\cdot36$; Hansen's adopted value of the latter being $12''\cdot17$, the value which best satisfies the observations discussed by Prof. Newcomb is found to be $8''\cdot8$. Though he considers this correction to the tabular acceleration to be clearly indicated, the residuals for the modern observations are yet of such magnitude as to be wholly inadmissible, and therefore the theory in its present state will not represent observations with any value of the secular acceleration, and respecting the cause of the magnitude of these remaining differences, he makes two hypotheses: (1) that they are only apparent deviations caused by inequalities in the earth's axial rotation, (2) that they arise from one or more inequalities of long period in the actual mean motion of the moon. Examining the effect of the first hypothesis, he arrives at the conclusion that if it be correct "the problem of predicting the moon's motion with accuracy through long intervals of time must be regarded as hopeless since it cannot be expected that variations in the earth's axial rotation will conform to any determinable law," and, he adds, "success in tracing the deviations in question to the moon itself and to the theory of gravitation is therefore a consummation to be hoped for." With regard to the second hypothesis, it is seen that the residuals of the equations of condition indicate that the modern observations may be nearly represented by a term having a period of between 250 and 300 years, and hence Prof. Newcomb inquires how closely an empirical correction to Hansen's first term depending upon the action of Venus, the period of which is 273 years, will accord with the modern observations, and he finds a very satisfactory agreement. An additional diminution of 10″ in the secular mean motion of the moon results, which at the present epoch involves a further diminution in the secular acceleration of $0''\cdot5$, that the ancient observations may be well represented; thus the acceleration becomes $8''\cdot3 \,.\, T^2$. A table is given exhibiting the corrections to Hansen's mean longitude from 1620 to 1900 for every tenth year; in 1880 it is $-11''\cdot2$, and in 1900 $-24''\cdot6$.

This important volume concludes with some remarks upon the bearing of the value of the moon's secular acceleration deduced from the investigations, of which we have endeavoured to give a general outline here. Prof. Newcomb thinks it is apparent that one of two propositions must be accepted: "Either the recently accepted value of the acceleration and the usual interpretation of the ancient solar eclipses are to be radically altered, the eclipse of -556 not having been total at Larissa, and that of -584 not having been total in Asia Minor; or the mean motion of the moon is, in the course of centuries, subjected to changes so wide that it is not possible to assign a definite value to the secular acceleration." It is certain that there will be a difference of opinion upon his main conclusions, and for this he expresses himself fully prepared. If a definite theory of the apparent inequalities of long period in the moon's motion cannot be formed, or if the moon's mean motion is subject to such changes from age to age that no invariable and well-defined value of the secular acceleration can be deduced, then he urges it is not certain that the question whether Hansen's tabular mean longitude during centuries preceding the Christian era does or does not require a considerable negative correction can ever be conclusively settled, since no conclusions can be drawn except from observations made near the period in question, and he advocates the necessity of a further investigation into the eclipses and other data on the two hypotheses, first that Hansen is correct during the period named above, and second, that a correction of $-16'$ is required, and suggests that the question should be examined in this manner by some independent authority. If, on the other hand, it is not possible to form a perfect theory of all the inequalities in the moon's mean motion independently of observations, he thinks it will be practicable to arrive at a value of the secular acceleration from the modern observations, reliable within $0''\cdot5$.

ROSCOE AND SCHORLEMMER'S CHEMISTRY

A Treatise on Chemistry. By H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S., Professors of Chemistry in Owens College, Manchester. Vols. i. and ii. (Macmillan and Co.)

THIS work is a most valuable contribution to the literature of chemistry. Its aim, as stated in the Preface, is to place before the reader a fairly complete, and yet a clear and succinct statement of the facts of modern chemistry, whilst at the same time entering so far into a discussion of chemical theory as the size of the work and the present transition state of the science permit, special attention being also paid to the accurate description of the more important processes in technical chemistry, and to the careful representation of the most approved forms of apparatus employed.

The manner in which this design has been carried out is such as might have been expected from the high reputation of the authors. The work commences with a very interesting historical introduction, in which the progress of chemistry is traced from the early times, in which it was merely an art subservient to alchemy, medicine, and a few branches of manufacture, to the time when, by the gradual accumulation of observations, and the discussion of them by men of philosophic mind, it rose to the rank of a science. A clear and impartial discussion is given of the relative merits of the various workers by whose labours the system of chemical philosophy now accepted was developed, showing how the phlogistic theory of Becher and Stahl first established a common point of view from which all chemical changes could be regarded,

and enabled chemists to introduce something like a system by which analogous phenomena could be classified and referred to a common cause; further, how the experiments of Black, Cavendish, and Lavoisier first showed the importance of attending, in the study of chemical changes, to the alteration in weight of the substances concerned; and how Lavoisier was ultimately led to the true theory of chemical combination, which regards it as consisting simply in the addition of one element to another, the weight of the product being exactly equal to the sum of the weights of the combining bodies.

Next follows a sketch of the labours of Bergmann, Richter, Cavendish, and others, which led up to the establishment by Dalton of the great doctrine of combination in multiple proportions, on which he founded the "atomic theory." The early experiments of Dalton are briefly described; his table of the relative weights of the atoms of certain elementary and compound bodies is given; and the Introduction ends with an account of the manner in which the exact values of the atomic weights were determined by Thomas Thomson, Wollaston, and more especially by Berzelius; of the discovery of the compound nature of the alkalis by Davy, and of a number of new elements by various chemists; and lastly, of the development of Organic Chemistry and its true relations to the chemistry of inorganic bodies; and the final establishment—chiefly by the researches of Liebig—of the fact that the science of Physiology consists simply in the physics and chemistry of the living body.

The Historical Introduction is followed by a chapter on the General Principles of Chemical Science, in which the methods by which the laws of chemical combination have been established are more fully described, especially that by which Lavoisier demonstrated the nature of combustion and the indestructibility of matter. This part of the subject is well illustrated by diagrams of the apparatus used in these important investigations. A list of the elements with their combining weights is then given, and a table exhibiting the arrangement of the elements in groups, chiefly, but not entirely, according to their combining capacity or quantivalence. Next follows a section on the laws of chemical combination, the methods of analysis and synthesis, the manner in which the law of equivalents and the law of multiple proportions were established, and the explanation of these laws by Dalton's atomic theory. This theory is adopted by the authors as the basis of all their explanations of chemical phenomena, and in this we think they are right: for without insisting on this theory as a matter of absolute certainty, we cannot but regard it as the only theory yet proposed which gives any rational and connected view of the laws of chemical action as established by experiment. There are, indeed, chemists of great eminence, who do not admit it, but hold out expectations of much more satisfactory explanations founded on dynamical views of chemical action. But these views have not yet been sufficiently developed to form a connected theory, and meanwhile we must make what we can of the theory of atoms, which, after all, is not necessarily inconsistent with any dynamical laws, or in other words, with any relations of matter to heat and electricity, that future experiment and observation may develop. There are, indeed, some philosophers who would have us believe in motion without matter, or in other words, in the movement of nothing at all; but this is high transcendental ground, on which we must humbly confess our inability to tread.

The consideration of the volume-relations of gases in combination, as established by Gay-Lussac, leads to the statement of Avogadro's law, according to which *equal volumes of all gases contain the same number of molecules.* This the authors rightly put forward as a hypothesis, the truth of which—like that of the law of gravitation—must be established by its accordance with the whole range of observed phenomena: for as such it must be received by the ordinary student, who is scarcely prepared to understand the manner in which it may be shown to follow as a necessary consequence of the kinetic theory of gases. An exposition is then given of the physical properties of gases, the continuity of the liquid and gaseous states, as demonstrated by Andrews, also a sketch of the kinetic theory of gases; and the chapter concludes with an explanation of the principles of Chemical Nomenclature and Notation.

The remainder of vol. i. treats of the Non-metallic elements. The preparation and properties of these bodies and of their compounds with one another, together with their industrial applications, are carefully described, and excellent figures are given of the apparatus employed for investigation and lecture illustration, also of manufacturing "plant." Especially worthy of notice are the illustrations connected with the manufacture of bleaching powder, sulphuric acid, and coal-gas. The volume concludes with a chapter on Crystallography, copiously illustrated with diagrams. The notation used is that of Naumann, which, for descriptive purposes, is perhaps the clearest and most graphic yet devised.

Vol. ii., part I is devoted to the general properties and classification of the Metals, and to the special description of those belonging to seven out of the twelve groups in which they are arranged by the authors. In this part of the work we find the same clearness and accuracy of description and explanation which are conspicuous in the first volume, both in the purely scientific portions and in those which relate to industrial applications. Excellent descriptions and figures are given of the manufacture of alkali and of glass, and of the metallurgy of zinc, copper, lead, silver, and mercury.

The book is well printed, and remarkably free from typographical errors. The few that we have noticed are not likely to mislead, and it is therefore not worth while to specify them, with the exception, perhaps, of one, occurring on p. 38 of vol. i., where it is said that the specific heats of the several elements are "universally" (instead of "inversely") proportional to their atomic weights.

The work, when finished, will afford the most complete systematic exposition of the existing state of chemical science that has yet appeared in the English language; and chemists will look forward with pleasure to the appearance of the second part of vol. ii., which will contain a description of the Iron manufacture, and to that of vol. iii., which will be devoted to the ever-growing subject of ORGANIC CHEMISTRY.

OUR BOOK SHELF

Manuals of Elementary Science—Crystallography. By H. P. Gurney, M.A. (Society for Promoting Christian Knowledge, 1878.)

THIS excellent little manual satisfies a want long felt, for, up to the present time, there was no book in which a general knowledge of the system of crystallography, first developed by Prof. Miller in his "Treatise on Crystallography," 1839, could be obtained. Prof. Miller's treatise and Tract are mainly occupied with the methods of calculation, and require a considerable knowledge of trigonometry. The manual before us aims at doing for these books what the crystyllographic introduction to Naumann's "Mineralogie" does for his "Lehrbuch der Krystallographie." It therefore avoids all the analysis used in the calculation of crystals, and limits itself to explaining the elementary geometrical principles involved in the representation of the faces by indices.

The method of development of systems of symmetry, rendered so familiar to us by Prof. Maskelyne, has been almost necessarily followed, and the author has consequently inverted the usual order of discussion of the different systems, beginning with the Anorthic, that of simplest symmetry, and proceeding through the different types of symmetry up to the cubic system, that of most complex symmetry. In the different systems the characteristic forms are shown to flow so simply from the conditions of symmetry that a moderately bright student ought to be able to deduce them himself after following Mr. Gurney's exposition in the first two or three systems. In his discussion of the rhombohedral system the author follows Prof. Miller. The hexagonal system, of which the rhombohedral is a hemisymmetrical development, is so imperfectly manifested by crystals that its discussion is only of theoretic interest and is unsuited to an elementary manual. In his discussion of merohedrism the author has not attended to the limiting condition, pointed out by von Lang, that the merohedral form should not be identical with the characteristic form of a system of lower symmetry, although here, likewise, he has the sanction of Prof. Miller's authority. The condition, however, is justified by the most recent observations, which have placed most of the minerals displaying such merohedrism in the systems of lower holohedral symmetry. We can heartily recommend the book to students even if they be able to study the more advanced text-books.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

On the Ancient Pitch of Organs

As I am obliged to intermit my researches on organ pitch for a few months, owing to pressure of other work, I wish to make a note of the point to which I have advanced, after consulting many old books, and actually measuring pitch and length of many old organ-pipes, for which I am obliged to the kind politeness of organ-builders, organists, and friends. When my researches are complete, they will appear with details in a paper to be read before the Society of Arts on the History of Musical Pitch, about a year hence. The delay arises from the difficulty of getting information from the Continent.

In England we have no organs older than the Restoration, 1660, as the Puritans smashed all church-organs in 1644-46.

The principle used by organ-builders was to make a certain pipe of the length of some multiple or easy sub-multiple of the standard length of measurement in their own country, and determine the other notes from its tone, according to the mean-tone or unequal temperament in universal use for organs everywhere till 1830, but beginning to be disused in France in 1834 and in England in 1854. There is an apparent exception in St. Jacobi Kirche at Hamburg, where equal temperament is claimed for 1720, when J. S. Bach played on that organ, and possibly in other old German organs. In England I have found the old unequal temperament still existing at St. George's Chapel, Windsor Castle, Kew Parish Church, St. Katherine's, Regent's Park, All Hallows the Great, Upper Thames Street, Maidstone Parish Church, St. Mary's, Shrewsbury, and several other organs which have been very recently re-tuned. The first equally tempered organ by Messrs. Gray and Davison was sent out in 1854.

The pitch note used from 1500 to 1650, at least in Germany, seems to have been F, for which a 13-foot pipe was employed for our F in the 16-foot octave. But the foot varied so much in Germany, being 3 per cent. longer than the English on the Rhine, and in Austria, and much shorter than the English in Central Germany, that the pitch thus determined varies by one to two equal semitones. The Brunswick foot, in 1620, where we have Prætorius's reference, possibly gave a tone of 35 vib. for the 13-foot pipe, an octave below the ordinary violoncello C.

In England Tomkyns (before the Commonwealth) fixes the F as 5 feet, which gives the A as 4 feet, and the double octave of this as 1 foot, and hence comes under the next category. The 13-foot F gives a 13-inch treble C, which, for Rhenish feet, would have a pitch of 425, whereas Handel's A was 423, having a pitch a minor third higher. This minor third constantly recurs. In Hamburg the St. Jacobi organ is a minor third sharper than the St. Michaelis organ, the first being a tone sharper and the latter a semitone flatter than French pitch. And strangest of all, the St. Jacobi organ had formerly one of its stops tuned to the low St. Michaelis pitch.

The old reason for fixing the pitch seems to have been to put the ecclesiastical tones within easy fingering for the organist, without using the chromatic notes (which *Arnold Schlick*, 1512, naïvely says is not convenient for most players), at the same time that they were within easy reach of a baritone voice. This is a point I have not yet worked out completely.

In England the foot-rule seems to have been generally adopted in early organs as the means of giving a standard, and it is not till about Green's time—a century ago—that I find it varied from this by a small fraction of an inch—not exceeding two-fifths.

The pitch of an open metal cylindrical flue-pipe used for the open diapason stop (but not "a show-pipe"), measuring 12 inches from the lower lip to the open end, varies from 472 to 475 vibrations in a second at 60° F. The variations are due to the size of the diameter, the force of wind, the opening at the foot, and the method of voicing. I have known such a pipe raised two vibrations in a moment by a slight alteration in voicing. This is the old standard pitch in England. Varieties depend upon the name of the note which it represents, and the classes of organs which I have met with in books or in reality, have hence been called by me the A foot, B flat foot, B foot and C foot organs.

1. The A foot organ has A 472 to 475. This was *Tomkyns's* pitch, as shown by Sir F. Gore Ouseley in his edition of "Orlando Gibbons," and seems to have been the pitch for which that composer wrote his Church music. It gives the mean tone C 565 to 570. As the French diapason normal is really A 435·875 (as determined originally by M. Cavaillé-Colt, and verified this year by Mr. Hipkins in Paris, by means of a Scheibler 440), this makes Tomkyns's pitch about three-quarters of a tone sharper than French pitch. This is the present existing pitch of St. Katherinen Kirche at Hamburg. The St. Jacobi organ, and also that in the Cathedral of St. Marie, at Lübeck, is a whole tone higher than French pitch. The great Franciscan organ at Vienna, 240 years old and untouched, gives A 460, which is only a semitone sharper than French pitch. These are the sharpest existing organs I have met with. The Franciscan organ is only used for the old ecclesiastical tone singing of the monks. This was also possibly the pitch recommended by *Prætorius* for church organs, the drawing in his book (1618) giving the B pipe one Saxon foot in length, with strong pressure of wind, and the Saxon foot being 7 per cent. shorter than the English.

It is as well to mention in passing that the tones and semitones here spoken of for measuring purposes, if not otherwise qualified, are *equal* semitones, and that, near enough for such purposes, an equal semitone and tone higher have 6 and $12\frac{1}{4}$ per cent. more vibrations, and thus a quarter and three-quarters of a tone higher have 3 and 9 vibrations more per cent. For unequal

or mean tone temperament, a *small* semitone has $4\frac{1}{2}$, a *large* one 7, and a tone 12 per cent. more vibrations. These numbers are very convenient for rough estimations.

The old French foot is 6 per cent. longer than the English, hence the one-foot pipe will be a semitone lower than the English, or about 443 to 446 vibrations. I have not met with a case of a French organ with A 443, or the one-foot pipe on A. But *Mersenne*, 1636, places the one-foot pipe on G, and this gives mean-tone A 496 and C 593. Now the St. Jacobi organ had actually A 491 and C 584 (equal temperament, making the C lower), as determined by forks tuned to the pitch and then measured. Hence, Mersenne's pitch, which even M. Cavaillé-Coll considered must be a mistake, actually exists at the present day.

2. The B flat foot organ, or B flat 472 to 475. This gives A 442, C 528, on the mean-tone temperament, that is, actually the pitch desired by the Society of Arts and not attained. This pitch was used by *Thomas Harris* in the Worcester Cathedral organ of 1666, by *Berhard Schmidt* (or Father Smith, as he has been called), in Durham Cathedral, 1683, Hampton Court, 1690, St. Paul's Cathedral, 1694-7, Trinity College, Cambridge, 1708, as I have ascertained, and probably in all his organs. It seems to have been occasionally used by the *Jordans*, who seem also to have built an A foot organ; but my inquiries are not yet complete. It is the favourite pitch of modern English organ builders, as I have ascertained by measuring the pitch-pipes of seven of the principal builders in London, which vary from C 524 to 528, at 60° F., to which all pitches are reduced.

3. The B foot organ, or B 472 to 475. This gives in England A 422 to 425, and C 506 to 512. This pitch was in general use, from at least 1700 to 1820, over England and over Germany. I found it in *Renatus Harris's*, All Hallows, Barking, 1675-7; St. Andrew Undershaft, 1696; and St. John's, Clerkenwell (date unknown); in *Harris and Byfield's*, St. Mary's, Shrewsbury; in *Byfield, Jordan, and Bridge's* two Great Yarmouth organs, 1733-40; in *Byfield and Green's*, St. Lawrence, Reading, 1771, and St. Mary's, Islington, 1772; in *Glyn and Parker's*, All Hallows the Great, Thames Street, 1749; in *Schnetzler's*, German Chapel Royal, St. James's Palace (date uncertain); in *Green's*, St. George's Chapel, Windsor, 1790; Winchester College Chapel, 1780; St. Katherine's, Regent's Park, 1778; and Kew Parish Church (date unknown). Glyn and Parker built the organ which Handel gave to the Foundling Hospital, 1750, and Handel, after conducting a performance of the "Messiah" there, in 1751, left his tuning-fork behind him. This fork is now in the possession of Rev. G. T. Driffield, Rector of Bow, and shows A 423, which is presumably the pitch of that organ. Mozart's clavier-maker, Stein, at Vienna, 1780-90, used a fork one vibration lower, A 422, which was undoubtedly the pitch of Haydn and Beethoven, and hence of Church music generally. It is a quarter of a tone flatter than French pitch. This was the pitch used when the Philharmonic Society was started in London, 1813, and was retained to 1826. Silbermann's organ at the Roman Catholic Church, Dresden, was about a comma flatter, or A 415.

4. The C foot-organ, or C 472 to 475 and A 495. The only instance known to me in England is Trinity College, Cambridge, as recorded in 1759 by the celebrated Dr. Robert Smith, its master, in his "Harmonics." But this was after its pitch (which was originally that of a B flat foot-organ) had been lowered a mean tone, by shifting the pipes, which, as he tells us, made it agree with the Roman pitch-pipes of 1702. But the French foot being a semitone flatter than the English, the Versailles B foot-organ (1786) had a pitch of A 396, C 474, as shown by the fork preserved in the Conservatoire in Paris, and hence precisely agreed with the altered Trinity College organ and the Roman pitch-pipe. Delezenne, in 1854, was fortunate enough to find an old dilapidated organ at the Hospice Comtesse, near Lille, which gave C 448, as near as he could measure, agreeing well with C 443, the calculated pitch of the French C foot organ.

This seems to be the first attempt at systematically finding the pitch of organs. The pitch of the pipes was in all cases found, when they could be actually heard, by beats with tuning-forks made for me, to the extent of an octave, on the basis of Scheibler's 256, 435, 440 (which I have reason to believe perfectly accurate), by Valantine and Carr, 76, Milton Street, Sheffield, and I have also reason to believe that these latter forks are not more than half a vibration wrong with Scheibler in any case. But before my complete paper is ready I shall have verified them by eighteen other forks of Scheibler now being very carefully copied at Crefeld. To hear the beats I stand thirty or forty feet away from the organ, and hold the fork over a resonance jar tuned to its pitch by pouring in water. The bellows is first filled, and no pumping is allowed during the ten seconds that I count. The beats are beautifully distinct, and I consider the result to be correct within one-fifth of a vibration.

The correction for temperature, which is most important (as at C 500 it is more than half a vibration per degree Fahr., to be added for higher and subtracted for lower temperature), is found by the following rule:—Add four per cent. to the number of vibrations observed, divide result by 1,000, and multiply by the number of degrees required. I have thus harmonised measurements made between 73° and 45° F.

The rule for finding pitch from measurement was given by M. Cavaillé-Coll (*Comptes Rendus*, 1860, p. 176), and, reduced to English measures, is as follows:—

Let L be the length, in English inches, of an open flue cylindrical metal diapason from the lower lip to the open end, and D its internal diameter, also in inches. The latter measure is frequently difficult to make, on account of the jagged, or "coned," or compressed, extremity. Then use the outer circumference, by wrapping a piece of paper round the pipe where it is truly circular; calculate the diameter as $\frac{7}{22}$ circumference, and throw off $\frac{1}{20}$ inch for the thickness of the pipe, to find D, which has to be known with considerable accuracy.

Let V be the number of double vibrations in the pipe, at 60° F., then

$$V = \frac{20080}{3L + 5V}.$$

I tried this formula with a whole octave of pipes at Green's St. Katherine's organ, and found that the error rarely reached one comma (or 1 in 80), which many persons can't hear, and never reached two commas (or 1 in 40). Since a quarter of a tone is 3 per cent. (or 1 in $33\frac{1}{3}$), and a semitone is 6 per cent. (or 1 in $16\frac{2}{3}$), this gives a far better knowledge than we can obtain by ordinary estimation of ear, without counting beats by measured forks.

It would confer a great favour on me if any one could give me these dimensions of old, unaltered organ pipes for the pipe which is nearest to twelve English inches in length, anywhere, especially abroad, naming the place and the note, and, if possible, date and builder, or would point out any existing unaltered old organs.

The Formation of Mountains

MR. ALFRED R. WALLACE asks one of our "great" physicists to enlighten us about the possibility of the interior of the globe "cooling more rapidly than the crust." If he will turn to a chapter on Conduction in such a work as Maxwell's "Theory of Heat," he will find an explanation of the principle. At p. 247 is a passage especially relating to the loss of heat by the earth.

But perhaps even a little physicist may help our great naturalist as the mouse did the lion.

In the first place it is of course understood that whenever it is said that "the interior of the globe cools more than the crust," it is not meant that it ever becomes cooler than the crust, but only that the interior, from age to age, goes on getting cooler than it was before, whilst the crust keeps at nearly a constant temperature.

An illustration, which I think gives a good idea of this process, may be taken from the dispersion of a crowd of persons in the street. Suppose each person to represent a certain quantity of heat. Then the number of persons in any space may be considered to represent its temperature, so that the crowded part will represent a very hot space. As the people disperse they move off the more quickly the further they get from the dense mass.

Now draw two lines near together across the street at some small distance from the densest part of the crowd, and let the space between these two lines represent the crust of the earth, while the space occupied by the crowd represents the earth's interior, and all beyond the outer line represents infinite space. Then the number of people passing outwards between the two lines at any particular moment will represent the quantity of heat in, and so the temperature of, the crust. At the

same time the number of persons remaining in the crowd will represent the quantity of heat in, and so the temperature of, the interior. Then it will be obvious that as the crowd disperses the number of persons at any one time between the lines may continue about the same (although the individuals will be changed), whilst those in the central crowd become fewer and fewer. This illustrates how the temperature of the crust may continue nearly uniform in spite of the continued loss of heat from, and cooling of, the interior.

I believe that I have long ago proved that the mere cooling of a solid earth would not give the amount of contraction needed to account for the observed inequalities of the surface, and I surmise that a diminution of the earth's volume has been caused by the escape of steam and gases from volcanic vents during past ages. This view has, however, attracted more attention in America than at home. O. FISHER

Harlton, Cambridge, December 13

Magnetic Storm, May 14, 1878

I AM inclined to think that Mr. Mance's observations (vol. xix. p. 148) upon the earth currents observed at Kurrachee must be incorrectly reported. To agree with the observations in China, Stonyhurst, Greenwich, and Haverfordwest, they should have commenced at 4 A.M. on May 15, and terminated at 5 P.M. on the same day (Kurrachee time).

It is a pity that electricians do not record these currents in absolute units. To say that the current was equal to fourteen Daniell cells means nothing unless the resistances present are also given. If an earth current is observed upon a cable it is easy to reproduce this current upon the same galvanometer with a known resistance and a known electromotive force, and then to express its value in webers or milliwebers. Thus if at Kurrachee 50° were noted on a galvanometer, and one Daniell cell reproduced this deflection through a total resistance of 125 ohms, then the current would be equal to $\frac{1}{125}$, or ·008 weber or 8 milliwebers, a magnitude which every electrician would understand. Moreover, if the length, resistance, and general direction of the cable or wire were given, as well as the direction of the current itself, the difference of potential of the earth at the two ends would be known. This if the cable were 246 miles long, and lay due east and west, and its resistance were 5ω per mile, then in the above case

$$\frac{E}{1230} = \cdot 008$$
$$E = 9\cdot 84 \text{ volts},$$

which is the difference of potential of the two ends.

If simultaneous observations were made in this way at numerous stations on the earth's surface, we should be able to plot out the distribution of potential on the globe, and arrive at some better knowledge of the cause of earth-currents than we have at present. W. H. PREECE

December 20

The Derivation of Life from the North

ATTENTION has been called by the President of the Royal Society to the labours of Mr. Dyer, as pointing in the case of plants to the conclusion that their various forms have been developed and dispersed from the north. I presume it is recognised that similar conclusions have been arrived at by Mr. A. R. Wallace in the case of animals. Mr. Wallace points to the palæarctic region as the great centre of their development or creation. On reading "The Geographical Distribution of Animals" when it first appeared, I was so much struck with the evidence adduced, that I was tempted to write and ask him if his work might not be said to occupy the following position in the history of unravelling what was formerly the mystery of geographical distribution. Mr. Darwin and others, including Mr. Wallace himself, had found a causal nexus in the case of islands, had shown that the faunas of islands had been derived from that of the nearest mainland, and in a character and degree varying concomitantly with the degree of their present disconnection therewith. They had thus completed the necessity for "centres of creation." Did not "The Geographical Distribution of Animals" afford the requisite evidence for carrying this commencement to its logical conclusion: for showing that in their turn the great continents themselves, or, more precisely, those which are outlying to the central mass (which is in the north, around the Pole), have a similar dependence, and have borrowed their own faunas from that northern mass, in a character and degree proportional to the dates and degree of their connection or separation from it, the islands might then be said to be the satellites, and the great zoological regions the planets of this system, all having borrowed their life directly or indirectly from a *single* "centre of creation."

To render this still clearer to my own mind I had a map of the world designed on a polar projection, the northern hemisphere being projected to somewhat beyond the southern tropic. By this means the manner in which the land surface of the globe is built around the pole is clearly seen, and the extremities of America, Africa, and Australia, extending into the great oceans of the world, are embraced, or nearly so. When the subdivisional regions (zoologically) of each of these great projections, and of the whole, are marked in colours, a succession of zoological strata, to speak rather inaccurately, appears. By carrying an ideal section from the supposed centre of creation in the north through either of these three great extremities, and from thence to the nearer, and afterwards the more remote, dependencies of those extremities (remote not in point of actual distance, as in degree of connection), we pass in each case through zoological strata of different types, until we arrive at those where no land-mammals are to be found at all. And this succession in space, as evidenced by geography, corresponds in a rough way with the succession in time, as revealed by geology. 1. As we recede in distance we meet with increased dissimilarity. 2. This dissimilarity partakes of a recession in type. 3. Some of these geographical districts seem to have their counterparts in geological periods. The Ethiopian region, as Mr. Wallace shows, presents us with the exiled miocene fauna of Europe in the most striking manner. Eocene forms may be seen in its dependency of Madagascar, or in the West Indies. Highly isolated Australia with its marsupials, &c., appears as if it were still in the secondary age. Oceanic islands, such as New Zealand, with a more beautiful climate, and more extensive surface than Great Britain, give us no land mammals at all. In others the reptiles "possess the land."

Mr. Wallace's plan is an excellent illustration of the comparative method, and shows how a careful classification leads to the solution of historical questions connected with the causes of that classification. Those causes are in this case comprised in the inference that a succession of waves of life has been propagated from the north, not all of which have had an equal extension, nor all encountered similar modifying circumstances.

If these inferences are not correct, perhaps Mr. Wallace would kindly set me right. J. W. BARRY

1, Duncombe Place, York

Glaciation of the Italian Lakes

HAVING spent some time lately on the border-land between Switzerland and Italy, it has occurred to me that a note on some glacial features of that region may prove of interest to the readers of NATURE.

The Lake of Lugano is a rock-basin. I believe it to have been scooped out by the glaciers which have formerly descended from the Alps. Of this there is abundant proof. The crystalline rocks in their lower reaches possess the easily recognisable outlines of *roches moutonnées*, but the stratified mesozoic rocks have lost these characters. Above Lugano and Agno these features are very well marked, and in these localities striation is tolerably frequent, the direction of the striæ being southerly. Along both sides of the southern extension of Mount St. Salvatore to Moreate, striæ can be seen in a few places near the lake-level, and the same is the case on both the Pianbello and Generoso shores. At the southern extremities of the lake are abundant moraine-mounds. Erratics are also present, most being gneissose or granitic, but a few have fallen upon the moving ice from nearer localities, as they are of dolomite. The moraine masses are cut through by the northerly flowing streams, but, after passing the parting between the waters flowing towards Lake Lugano and those running into Lake Como, there is the appearance of great destruction of the moraines. Unfortunately I had a mere cursory glance down the Val della Tresa, through which the drainage of the lake flows to Lago Maggiore. It has often been remarked that in this South Alpine lake district, the *débris* left by the glaciers is exceedingly small when contrasted with similar regions north of that moun-

tain chain. To every observer, indeed, this must be obvious. Two reasons have been adduced in explanation—1. That the glaciers have been smaller from the cold of the glacial period not having extended over Italy, as indicated by the absence of the reindeer and other sub-arctic species from the drift; 2. That denudation has been enormous. In spite of the southern exposure it hardly appears probable that there could have been sufficient difference in the size of the northern and southern glaciers to cause this contrast, as long as the glacial period lasted, for the vapour-laden winds from the sea must have deposited much of their moisture on the southern slopes as snow. But, as the ice-age passed away, the southern aspect of the Alps would doubtless be freed from its influence sooner than the northern, and hence, while snow and ice reigned in the latter area, the regions south of the mountains underwent denudation, probably, for a vast period. I would therefore suggest that the comparatively small amount of glacial *débris* on the southern side of the Alps may arise from that region having been exposed for a much longer time to sub-aërial waste, and in particular to the floods caused by the more rapid melting of the snows on the southern slopes of the mountains. GEO. A. GIBSON

Electric Lighting

IN the *Proceedings* of the Philosophical Society of Manchester Mr. Wilde has described a new electric lamp, in which the carbons are placed parallel to each other, as in a Jablochkoff candle, but without any insulating material. It may not be apparent to all why the arc always locates itself at the extremity of the pair of carbons, and this, as Mr. Wilde observes, whether the lamp be erect or inverted. The explanation is that the current in each carbon repels the electric arc exactly as the current in the mercury-troughs repels the connecting cross-wire in a well-known experiment of Ampère. In Wilde's candle we have two fixed conductors, the carbons, and a movable conductor, the arc. Since the current in the arc and the current in either carbon are one from the other towards the point of junction of that carbon with the arc, the arc must be repelled by the carbon. One cannot but be surprised that Ampère's experiment did not suggest the discovery made by Mr. Wilde, that the insulating material might with advantage be omitted in Jablochkoff's candle. J. HOPKINSON

4, Westminster Chambers, December 12

The Reproduction of the Eel

THE time of spawning and the differences between the sexes of the common eel has been hitherto unknown. Last year for the first time in this country eels (*Anguilla bostoniensis*) containing eggs were found, December 31, by Mr. Edwards, at New Bedford, Mass., as stated by Mr. Putnam in the *Proceedings* of the Boston Society of Natural History. From observations on eels brought me at Providence, R.I. it appears that eels spawn here in salt or brackish water from October to the end of November, as I have found several eels containing eggs which seemed nearly ripe, the ovary being full and large. To-day on examining the testis of a male eel 17 inches long, the mother-cells and sperm-cells were found, the latter numerous and lively, from $\frac{1}{3000}$ to $\frac{1}{20000}$ inch in diameter. The eggs were white, just large enough to be distinguished by the naked eye, measuring a little less than $\frac{1}{2}$ mm. in diameter. The females are larger than the males, with the belly white, while the males are easily distinguishable by the dark bellies and a narrow silvery or golden median stripe. A. S. PACKARD, Jun.

Laboratory of Brown University, U.S., November 27

AERATED BREAD

SOME remarks upon aerated bread which were made by Dr. B. W. Richardson at the recent general meeting of the company working Dr. Dauglish's patents require examination. Now it is noteworthy how imperfect our knowledge of the chemistry of the mill-products from the cereal grains still remains. Without such knowledge we are not in a position to dogmatise as to the exact nutritive values of different kinds of bread. As I pointed out in a previous article on "Real Brown Bread,"[1] the statement that whole wheaten meal, bran, pollard, &c., contain more nitrogen, and therefore more flesh-formers than fine flour, rests upon no certain basis of analytical fact. And if it were proved that all the nitrogen of the most nitrogenous of mill-products does really exist in what are called albuminoids or flesh-formers, we cannot ignore the presence of much indigestible fibrous material in bran and pollard, material which is not only non-nutritive itself, but which locks up in an inaccessible form much of the real nutrient substances associated with it. Thus a sample of wheaten bran, or rather, fine pollard, may refuse to give up to the boiling dilute acid and alkali used in fibre-determinations more than six-sevenths of its nitrogenous matter; and it can hardly be expected that the secretions of the alimentary canal will prove successful in withdrawing a larger proportion. Indeed, the analysis of the residues of such foods after having been submitted to the digestive process, has confirmed this expectation in the case of the human subject. Moreover, while a not inconsiderable part of the albuminoid matters of the outer coverings of the grain thus escapes digestion from its mechanical condition, there is good reason to believe that a further portion remains unabsorbed, by reason of the rather hurried passage of the branny particles through the digestive tract. And the same causes which operate to prevent a part of such flesh-formers as exist in the bran from being utilised, affect also and in a similar way the useful mineral substances which abound in the coarser mill-products, as well as the oil or fat which they contain.

Now let us see what are the distinctive advantages claimed for Dr. Dauglish's bread-making process by Dr. Richardson. It yields a bread which is said to be "perfectly clean, perfectly wholesome, and completely nutritious." As to the perfect cleanliness of this mechanical process for making bread there can be no question; it is immeasurably superior to the barbarous and old, but, as Dr. Richardson remarked, *not* "time-honoured system of kneading dough by the hands and feet of the workman." And we may agree, with almost equal confidence, in the statement that aerated bread is perfectly wholesome. The stream of pure water charged with carbonic acid gas vesiculates the dough, which has required neither alum, nor blue vitriol, nor lime-water, to check the irregular fermentation, and neutralise the sourness of mouldy or otherwise damaged or inferior flour. But, on the other hand, the adoption of the aerating process does not of itself necessarily exclude *all* adulterations of the bread: materials to whiten the loaf and to cause the retention of a larger percentage of water may still be used. As to the small loss of nutrient materials involved in the ordinary fermentation of dough, it hardly merits consideration. Perhaps Dr. Richardson alluded to it because it gave him an opportunity of having a fling at his old enemy, alcohol, of which it has been found that a newly-baked loaf, made by means of yeast, contains about 0·25 per cent. So that a man who eats twenty quartern loaves has therein consumed an amount of alcohol which is commonly contained in one bottle of port! But if there be no really serious loss of starch by conversion, first into sugar, and then into carbonic acid gas and alcohol, there can be no doubt that a number of altered products are present in a fermented loaf, and that these are less abundant and less variable in nature in aerated bread. But the presence in fermented bread of larger quantities of sugar, gum, and soluble starch than are found in aerated bread is not usually a disadvantage so far as the digestibility of the loaf is concerned. It is rather to the production of lactic acid and of nitrogenous ferments by the use of yeast or leaven that we should attribute the uncertain value of ordinary bread. The quality of the yeast, too, must not be left out of consideration, as some of our home and of our imported supplies are by no means of a satisfactory character.

[1] See NATURE, vol. xviii, p 229.

I may now discuss the third meritorious feature which Dr. Dauglish regarded as a conspicuous advantage possessed by his process—a view which is now endorsed by Dr. Richardson. We are told that "in brown bread, which contains the envelopes or coverings of the whole grain, the flesh-formers amount to 10 per cent., and that, while it is possible to live upon brown bread, without any other food, the health suffers, and death finally ensues, on white bread alone." "The flesh-formers in white bread amount," we are told, "to 7 or 8 per cent." Now by the use of the aerating process, a light and palatable loaf may undoubtedly be readily made, either from the entire meal of crushed wheat, or from such meal from which nothing but the long or coarse bran has been excluded. Such a result cannot be secured with any degree of certainty when yeast is used. This is quite true. But it is not by any means an ascertained fact that brown bread or whole meal bread contains a larger proportion of flesh-formers than white bread from the same wheat. If we make no deduction on account of insoluble and inaccessible flesh-formers in the coverings of the grain, we shall have to make a very considerable deduction on account of nitrogenous matters which are not really albuminoid or flesh-forming, and which are extensively present in the coats which form the main substance of pollard and sharps. We can hardly attribute flesh-forming properties to the "diastase," "cerealin," and other obscure nitrogenous ferments which we know to abound in the coarser mill products. Now these are the very bodies which the aerating process enables us to include in our bread without making it heavy, the very bodies whose presence contributes most largely to raise the percentage of assumed flesh-formers, from the 7 or 8 per cent. in white bread to the 10 per cent. in real brown bread. Now, although we have no absolute method of distinguishing between the true flesh-forming nitrogenous bodies in food-stuffs and those whose value is at the best problematical, yet the "carbolic acid process" which I devised in 1873, and which has latterly been attracting a good deal of attention, furnishes some instructive results when applied to the various mill products of the cereals. For instance, I found (in 1875) that pearl barley contains at least 92 per cent. of its nitrogen in the form of genuine coagulable albuminoids, but that "fine dust," consisting of the richest parts of the barley grains, though it contains three times as much nitrogen as pearl barley, does not contain twice as much unmistakable flesh-forming substance. A similar observation was made on comparing the coverings of the wheat grain with the flour—93 parts out of every 100 of nitrogen in ordinary wheaten flour being certainly in the form of flesh-producers, while the proportion in the entire bran sinks to an average of 72, and sometimes touches a much lower figure. The same result has been obtained with a large number of food materials, in some succulent vegetables the albuminoid nitrogen not exceeding one-fifth of the whole.

It is evident, from the preceding considerations, that whatever be the nutritive or medicinal merits of whole-meal bread, it cannot be definitely stated to be a much richer food so far as flesh-formers are concerned, than white bread made from the flour of the same sample of wheat grain. If we deduct from the supposed 10 per cent. of flesh-formers in whole meal bread $\frac{1}{5}$ or 2 per cent. because of the existence of non-albuminoid nitrogen in the branny particles, and because of the indigestible condition of a small part of the true albuminoids, we leave but 8 per cent. a proportion which does not greatly exceed the 7 or $7\frac{1}{2}$ per cent. usually attributed to white wheaten bread.

On some future occasion I may have a few words to say, should the Editor of NATURE accord his permission, as to the bread question treated of in the "Dietaries of Prisons' Report," lately presented to Parliament.

A. H. CHURCH

ON THE COMBUSTION OF DIFFERENT KINDS OF FUEL

OUR attention has been called to this subject on perusing a paper read before the American Institute of Mining Engineers. In this communication it is attempted to be proved, that the manner in which charcoal unites with oxygen in iron furnaces, explains its alleged superiority over mineral coal.

The question appears to us to involve considerations outside the mere technical limits of iron smelting. We therefore submit the following remarks, which have been prepared at our request, by a gentleman whose important researches on the economic application of fuel in the smelting of iron are known to all the world.—ED. NATURE.

Prof. John A. Church, of Columbus, states, in a recent publication, "that it is a well-known fact that under similar conditions a ton of pig-iron can be made from any ore with less fuel when charcoal is used than when coke or anthracite is employed for heating." He then discards, as untenable, all former explanations of this doctrine proceeding either from scientific or practical men, and maintains that "the highest carbon duty is given by the fuel which withdraws the most oxygen from the blast in a given time."

The professor afterwards proceeds to explain that charcoal, being highly porous, presents a more extended surface to the action of the oxygen than the more compact forms of carbon as it exists in coke or anthracite. He then considers the effect of what is designated in the paper as diluted oxygen on its way to the upper regions of the blast furnace.

In this latter statement with regard to free oxygen, it seems to be overlooked that whatever difficulty this gas may have in attacking dense carbon, there can be no reason why carbonic oxide, generated from coke or anthracite, should not be as easily burnt to the state of carbonic acid as the same carbonic oxide is burnt when formed by the combustion of charcoal.

If it could be shown that all the carbon consumed in the hearth of the blast furnace were in the condition of carbonic acid, then, no doubt, free oxygen might be expected there, but in the presence of so vast a volume of inflammable carbonic oxide in that region such a condition of things is scarcely possible.

It is unnecessary, however, to occupy space with merely speculative matter when actual analyses inform us that in a furnace using coke, not only is there no free oxygen at a very short distance from the tuyeres, but that there is no carbonic acid. In point of fact the whole of the gaseous carbon exists there in the form of carbonic oxide.

Admitting, then, the highest carbon duty to be dependent on the law laid down in the paper, it is clear that at a distance of two or three feet from the point where the blast enters, the conditions in this respect of a furnace burning charcoal or coke are the same.

Prof. Church quotes, in the course of his observations, the results obtained from two furnaces, one using charcoal the other anthracite, and from these he infers that there is an "inherent difference" between the two kinds of fuel of 900 lbs. per ton of iron in favour of charcoal. This figure is a mighty one when it is considered that the charcoal actually consumed for each ton of pig is under 1,800 lbs.

Somewhat inconsistent with this conclusion is the instance quoted of a Lake Champlain furnace, where the consumption of anthracite has been reduced nearly 25 per cent. below that quantity which formed the basis upon which the "inherent difference" was estimated.

The paper further recommends as a reasonable consequence of the superiority of charcoal over coke, that iron manufacturers should, as far as possible, imitate the physical structure of the former in the produce of their

coke ovens. Our "perversity" in preferring hard to soft coke is condemned, and we are invited to put reason in the room of traditions which have not "one recorded fact to sustain them."

My attention, as an iron-smelter, was drawn to the very small consumption of charcoal in a certain instance quoted by Prof. Tunner, of Leoben, and being unable to reconcile his experience with my own observations, I obtained from this respected authority further confirmation of the exactness of his figures. Along with this he kindly repeated his analyses, including one not given in his original paper, viz., that of the gases taken on leaving the furnace, in other words, after they had *completed* their work.

Other investigations prevented my examining the question at the time with that attention it deserved, and I concluded, upon other grounds than those advanced by Prof. Church, that there was some actual difference in the mode in which charcoal effected the reduction of at least *some* ores.

In this I now think that I was mistaken, and I will endeavour to prove that the author of the paper commits a grave error in comparing two blast-furnaces working upon different kinds and quantities of ores and flux used in the production of pig-iron. I will also attempt to demonstrate that the use of hard coke, held to with such "singular perversity," can be maintained by "reason" as well as by "tradition."

Carbonic oxide, as is well understood, is the chief reducing agent in the smelting of iron, and for our present purpose we may regard it as the only substance which deprives the metal, as it exists in ores, of its oxygen. The carbonic acid which is formed by this deoxidising action possesses a tendency, at certain temperatures, diametrically opposed to that of the lower oxide of carbon—it reoxidises the iron.

This conflicting property of the carbonic acid is kept in check, in iron smelting, by the presence of carbon in the form of its lower oxide, being about double that which is present in its highest form of oxidation.

When I came to examine the ratio in which the carbon in these two conditions existed in the escaping gases, as described privately by Prof. Tunner, I observed that they agreed very nearly with that which I imagine constitutes, in furnaces using coke, a state of equilibrium between the gases and the ore in the process of reduction.

Now no one will dispute that when two pounds of carbon are burnt to the state of carbonic oxide and one pound to the form of carbonic acid the quantity of heat is the same, from whatever source the carbon itself may be derived.

If, after having determined a perfect resemblance between the extent to which the fuel has been oxidized, in the furnace, when using charcoal and using coke, we find that there is no difference in the amount of heat wasted, it is time to consider whether the pig-iron itself, obtained by means of these two kinds of fuel, may not require very different quantities of heat for its production.

It may be here stated that the Cleveland furnaces in England, with which I compared those of Carinthia, were consuming 21 to 22 cwts. of coke against 14 or 15 cwts. of charcoal used in the latter per ton of iron. The weight of the slag produced in the former was very much the larger of the two. The additional heat absorbed in fusing this substance was further augmented by that required for the decomposition of silica and phosphoric acid, the bases of which are found more largely in Cleveland than in Carinthian pig. The diminished quantity of fuel burnt in the charcoal furnaces reduces very greatly the weight of gases, and this consequently lessens the amount of heat carried away through their instrumentality.

The following figures exhibit the number of centigrade heat units required, according to my calculations, per unit of each kind of pig-iron referred to.

	Cleveland iron.	Carinthian iron.
Evaporation of water in fuel	15	15
Reduction of oxide of iron and dissociation of carbonic oxide	1730	1730
Expulsion of carbonic acid from carbonate of lime	250	25
Decomposition of this carbonic acid	265	25
,, water in blast	130	75
,, silica and phosphoric acid	200	50
Fusion of iron	330	330
,, slag	830	330
Loss by radiation	270	200
Carried off in gases	440	210
	4460	2990

Now when the proportions between the heat requirements and fuel-consumption come to be examined, we find that the two sets of numbers agree almost exactly; for—

$$4460 : 2990 :: 21 : 14{\cdot}08$$

Since writing on this question, nearly seven years ago, I have had frequent opportunities of examining the performance of charcoal-furnaces in Sweden, Italy, and Spain, as well as in Virginia, Kentucky, Ohio, Missouri, and Michigan, in the United States. I soon became aware that different kinds of ores demanded very different quantities of charcoal for their treatment. In some cases the weight was nearly as low as that consumed in Carinthia, in others it was quite as much as if coke had been the fuel employed. I failed on every occasion to detect any circumstance beyond the change in the ore itself, or in the nature of the iron it afforded, to which I could ascribe the difference in question. All doubt, however, on the supposed difference of value between the vegetable and mineral fuel was dispelled on receiving from the owners of works in the North of Spain and in Virginia, statements from their books exhibiting the smelting of the same ores with the two kinds of fuel. The difference in these was often in favour of the coke, but such difference as existed could easily be accounted for by fluctuations in the amount of foreign matter in the fuel, or in small changes in the quality of the ores.

It only remains for me briefly to mention the grounds upon which, for chemical reasons, hard coke may be superior to that softer variety recommended by Prof. Church.

Carbonic acid, as is pointed out in the paper by this author, possesses the power of dissolving carbon, and every pound so dissolved involves a double loss. There is a reduction of temperature where the action takes place, and there is a pound less of fuel remaining to be burnt at the tuyeres. I ascertained, however, by direct experiment, that all forms of carbon are not equally easily affected by carbonic acid, that in hard coke being capable of resisting the solvent action much better than the same carbon as it occurs in soft coke. The importance, therefore, of employing our fuel in that condition where it is least susceptible of being oxidized in the region of the furnace where its combustion is useless, need not be further insisted on.

I am ready to admit with Prof. Church, that the traditional opinions of practical men have often required correction from scientific investigation, but upon the present occasion, so far as I have been able to judge, the ironmaker and the chemist agree in the relative value of hard and soft coke. I. LOWTHIAN BELL

PAPUAN HERPETOLOGY[1]

In this memoir, which forms a portion of the thirteenth volume of the *Annals* of the Civic Museum of Genoa, we have by far the best account of the herpetology of

[1] "Catalogo dei Rettili e dei Batraci raccolti da O. Beccari, L. M. D'Albertis e A. A. Bruijn, nella sotto-regione Austro-malese." Por W. Peters e G. Doria. *Ann. del Mus. Civico*, Genova, vol. xiii., 1878.

the great Papuan subregion, that has hitherto appeared. At the same time the authors have not attempted to make a perfect faunistic work of it. Only such species as are represented in the collections made by the Italian travellers, Beccari and D'Albertis, on their various joint and several expeditions, and in the collections sent to Genoa, by Herr Bruijn of Ternate are enumerated in the list. On the other hand the mass of these collections is so great—consisting of 3,000 examples from 44 different localities, and the series thus brought together is so much more nearly perfect than that which any other authors have had before them—that the result has been to give us an excellent idea of the general character of the reptiles and batrachians of this division of the earth's surface. Let us, therefore, look through the pages of Messrs. Peters and Doria's excellent memoir, and see what general views we can obtain from it as to the peculiarities of this little-known branch of the Papuan fauna.

In the first place, land-tortoises are few in the Papuan sub-region. Our list contains but two species, one from Amboina and Celebes, the other from the southern extremity of New Guinea, and very doubtfully distinguishable from an Australian species.

Crocodilians are also scarce. The series contained examples but of one species—*Crocodilus porosus*—which extends from India into Northern Australia.

Of lizards, besides the monitors, of which genus not less than 16 species are contained in the list, the great mass are Skinks, Geekos and Agamids. As in Australia the Skinks are especially numerous, upwards of 30 species being represented in the series, of which 8 are now described for the first time.

The ophidians are also well represented in the Papuan fauna, the series examined by our authors affording examples of 54 species. Amongst the Boas *Liasis* and *Chondropython* are characteristic Papuan forms, whilst the Australian *Morelia* also extends into New Guinea. But no greater sign of the essential unity of the Australian and Papuan faunas can be shown than the presence in New Guinea of the three Elapine genera, *Diemenia*, *Pseudechis* and *Acanthophis*, all characteristic forms of the Australian continent. At the same time the presence of an *Ophiophagus* in New Guinea, proves that an intruding element from the north has reached thus far.

About 20 batrachians close the list, amongst which *Limnodytes* and *Hyla* seem to be the most prevalent genera. The Australian *Pelodryas cærulea* is abundant all through the sub-region. A new and very singular form obtained by Beccari in the interior of New Guinea, near the river Wa-Sampson is characterized as *Sphenophryne cornuta*, and a second, obtained, by the same explorer on Mount Corfak as *Xenobatrachus ophiodon*. The latter shows some points of affinity to the Australian *Myobatrachus*.

Seven excellent lithographic plates illustrate some of the rarities described in this memoir, and two maps are added to show the exact localities where the collections were found. The maps we see with great pleasure, as in our opinion no zoological work of a faunistic character can in these days be considered complete without such an appendage.

THE METEOROLOGICAL SOCIETY LECTURES

A COURSE of six lectures on meteorology was recently delivered under the auspices of the Meteorological Society at the Institution of Civil Engineers. The purpose of these lectures, we believe, is to spread a knowledge of the known facts and principles of meteorology, and in this useful mission we cannot but wish the Society every success. We here give abstracts of two of these lectures, by Mr. J. K. Laughton and the Rev. W. Clement Ley. The subject of Mr. Laughton's lecture was—

Air Temperature, its Distribution and Range

After calling attention to the importance of climatic knowledge the lecturer dwelt on the fact that though all heat as affecting climate emanates directly or indirectly from the sun, temperatures have but little relation to latitude except when the distances are very great. He illustrated this by reference to isothermal and isabnormal maps, and went on to speak in some detail of the several causes of the disagreement between isotherms and parallels of latitude. Locally there is a very great difference between the temperatures of adjacent localities on account of the sunny aspect or sheltered situation of some as compared to others, as is found in an extreme degree in such places as the Undercliff of the Isle of Wight; but geographically, a cause of very considerable importance is the nature of the soil. The air over sandy or sterile ground is heated by direct contact and by radiation, to a degree far in excess of what happens to air resting on grass-grown or verdant plains; heat proceeding from an obscure source is unable to escape through the air, just as obscure heat-rays may be caught and accumulated in a closed conservatory or in a glass-covered box, so that the air may be raised to a very high temperature: several instances are on record of a temperature of 130° F. being observed under such circumstances. On the other hand, when the solar heat falls on ground, whether grassy or snow-covered, that will not easily part with it, the air may remain cool, or even cold; as is found in our every-day experience in summer of the pleasantness of a field path as compared with a high road; and as is shown more markedly by the great power of the direct rays of the sun in the Arctic, or at elevated stations in the Alps or Himalayas, whilst the snow is lying all around, and the temperature of the air is far below freezing-point.

But greater far than the effects of differences of soil are the effects of ocean currents, which warm the air to an almost incredible degree. Mr. Croll has calculated that the surface-water of the North Atlantic, if deprived of the Gulf Stream, would be reduced to a temperature very far below freezing-point; that the heat which the Gulf Stream disperses into the superincumbent air would, if converted into power, be equal to the united force of some 400 millions of ships such as our largest ironclads. This heat, thrown into the air, is wafted by the south-westerly winds over the north-west of Europe, and very largely over our own country. It is this that makes the extreme difference between the climate on this side the Atlantic and that on the other, that gives us green fields and open harbours during the winter, whilst in Labrador or Newfoundland they are buried in snow or choked with ice.

The carrying power of water is so great as compared with that of air that the climatic effect of winds heated by contact with hot earth is relatively small. The scirocco of the Mediterranean, a wind heated over the great African desert, has often been referred to as the "snow eater" of Switzerland. This has been proved to be a mistake. The snow-eating wind of Switzerland is a wind from the Atlantic, warmed by the Gulf Stream, and rendered dry and hot by the condensation of its vapour as it passes over the mountains. Similar winds have been observed in many different parts of the world—in New Zealand, in Norway, in Greenland, and in North America, where their peculiar dryness, carrying off all moisture, renders the grass so inflammable that the smallest accidental spark lights up a fire which may spread over a country, and is thus the true cause of those immense prairies which are a distinctive feature of North American geography. But such hot winds are quite distinct from such winds as blow from the Sahara, or the Stony Desert of Australia, or from many other sterile tracts of country; winds which are merely the escape of air heated to an extreme degree by contact with the burning soil. These hot winds are for the most part merely disagreeable; but cold winds are very often dangerous; in the North-Western States of America a cold wind, ushering in a violent snow-storm, caused the death of more than 300 people in January, 1873; and in many other localities, a cold wind bringing in a sudden fall of temperature through 40 or 50 degrees, is always a cause of grave anxiety. Our English "Blackthorn Winter" in April or May is only one, and a subdued instance of the ill-effects of such cold spells.

The presence of moisture in the air, by checking radiation from the ground by night, or during the winter, softens the rigour of the seasons, makes the summers less hot, the winters less cold. It is this that constitutes the difference between "insular" and "continental" climates; it is the want of the vapour-screen which causes "excessive" climates such as we read of

in the far east, where, as near Khiva, a summer of more than tropical heat is succeeded by a winter of Arctic rigour. In a very extreme degree the climate of Astrakhan contrasts with that of Fuegia, and yet the mean temperature of the two is about the same; but in the one the seasons are excessive, in the other the difference is but small. The difference in the products of the two countries is thus very great: on the one hand, plants requiring great heat, but able to withstand the cold, on the other plants of a more tender nature which can flourish with a very moderate amount of warmth; in the one grapes and corn, in the other fuchsias and veronicas.

In studying climate it is therefore necessary to observe not only the greatest heat and the greatest cold, but also the mean temperature. These can only be observed by means of thermometers, for personal feelings may be the effects of many other causes—of wind or evaporation, or state of health, or peculiarity of constitution, and are absolutely no index to the state of the air temperature.

The lecturer then proceeded to speak of the different kinds of thermometers, several of which were exhibited, and of the several stands for sheltering them. The Meteorological Society has decided positively in favour of the Stevenson stand, and directs its observers to record the temperature at 9 A.M. and 9 P.M., as well as the highest and lowest, as registered by the maximum and minimum thermometers. He then described some novel and ingenious contrivances for automatic registering, such as the "turn over" of Messrs. Negretti and Zambra, and the "chronothermometer" of Mr. Stanley, and concluded by pointing out that these instruments were but a means to an end, and that the study of climate was the study of nature in one of her most beautiful and most varied aspects.

Mr. Ley's lecture was on

Clouds and Weather Signs

The lecturer dwelt, in the first place, on the unsatisfactory condition of this portion of meteorology, as contrasted with those branches of the science in which instruments are employed. The great impediment to our progress arises from the fact that cloud-observation is, in large measure, an incommunicable art, requiring a special training of the eye. Specimens of the objects of study cannot be exhibited, neither is it possible, in illustration of the subject, to refer to types of cloud depicted in the well-known paintings of the best artists, because the latter, aiming at the production of atmospheric effects, employ the materials most easy to handle, which are commonly the least typical cloud-forms. The old classification and nomenclature of clouds is highly unsatisfactory, having been framed at a time when the relation of wind and weather to the distribution of barometric pressures was unknown; and with this relation the forms and movements of the clouds are intimately connected.

As regards configuration, clouds seem naturally divisible into two groups, those which arrange themselves in layers, whose vertical diameter is small as compared with its horizontal, and those which assume spherical or hemispherical shapes; and this division is related to certain physical conditions of the atmosphere and of the earth's surface beneath the cloud. It is, however, essential that we should possess some name or system of names to distinguish those clouds which are conveyed by the upper currents, and the term cirrus, with its compounds, must be more closely restricted to this class of clouds than has yet been done. From the use of weather-maps a new science of the winds has originated, on which all attempts at weather forecasting must be based. The movements of the upper clouds afford most valuable information concerning the distribution and movement of the areas of high and low barometric pressure. Rules by which this information may be interpreted, based in great measure on a former investigation by the lecturer,[1] are somewhat complex, and cannot well be given in a brief *résumé* like the present.[2] It may be sufficient to explain that in the front of an advancing barometric depression there usually extends a bank of the halo-producing cirro-stratus, the exterior edge of which is, roughly speaking, a parabola, the focus of which lies in the line about to be traversed by the centre of the depression. On the right-hand of the centre this bank or sheet is abruptly broken and is succeeded in the rear by local shower-clouds. On the left-hand the sky commonly continues overcast, but the cloud-plane gradually descends until little is to be seen but low stratus. A backing of the upper current takes place until after the centre of the depression has passed. In whatever direction a depression is advancing the same characteristic phenomena are observed. Thus changes in the clouds indicate to us probable alterations of wind and weather.

[1] "Relation between the Upper and Under Currents of the Atmosphere around Areas of Barometric Depression." *Quart. Journ.* of Met. Soc. vol. iii. p. 437.

[2] The lectures will shortly be published.

While the nimbus, which exists in the front of a depression, first makes its approach evident by changes in the higher cloud-strata, the process of nubification is the converse of this in those local showers which commonly occur on the right-hand and in the rear of a centre of depression, and therefore when the barometer is rising or just about to rise. These latter are developed in an upward direction through the formation of cumulus. The precipitation which occurs in them—always preceded by a change of appearance in the domes of cloud, which assume a soft and cirriform aspect—is attributed to the neutralisation of electricities as the summit of the cloud passes into a higher region; but there are important differences of appearance between those cumuli which are likely, and those which are unlikely, to undergo this transformation,

A physical explanation is given of the ordinary weather signs derived from the colours of the sky, from "visibility," and from unusual refraction. Attention is invited to some peculiar types of cloud, especially to a very elevated turreted stratus, often erroneously termed cirro-cumulus, occurring with high temperature on the south-western borders of anti-cyclones, a forerunner of thunderstorms. The formation of the low-level stratus and of the fog which usually prevails in our winter anti-cyclones, seems to be due to a downward movement of the air at a time when the earth's surface is colder than the atmosphere at a slight elevation above it.

In the course of this lecture sketches of some of the more definite varieties of cloud, with arrows indicating the direction of the currents, and a diagram showing the movements of the upper currents, and the prevailing cloud-types around areas of depression, were exhibited by the aid of the oxy-hydrogen lime-light.

THE MOTION OF A LUMINOUS SOURCE AS A TEST OF THE UNDULATORY THEORY OF LIGHT

1. ALTHOUGH the undulatory theory of light may now be considered as completely established, still any confirming test of a physical theory is in itself interesting as a fresh illustration of a natural truth. Considering how at one time crucial tests of this theory were sought after, it would appear perhaps rather an anomaly that attention should apparently not have been given to the effect attendant on the motion of a luminous source as a test between the two rival (undulatory and corpuscular) theories, and that more especially as the test would appear to be in principle a simple and decisive one. I should have considerable diffidence in directing attention to this point, but no record apparently exists of experiments proposed or attempted with this view. It might be said that the possible existence of practical difficulties in the way of carrying out the test may account for this; but then practical difficulties are seldom allowed to stand in the way, if a theoretic *principle* be correct; and, unless a thing were seriously proposed and discussed, no attempt would be made to surmount the difficulties that might exist in the way of carrying it out. Sir John Herschel, as far as he touches on this point, would appear to have had the idea that such a test between the two theories could not, *in principle*, be applicable; for he says ("Outlines of Astronomy," p. 214), speaking of the effect attendant on the motion of a luminous body, "The effect in question, which is *independent* of any theoretical views regarding the nature of light, ... &c." It is true he mentions afterwards, in a foot-note, a difference in the effect in the case of the two theories as regards the *velocity* of light, in the case of a luminous source moving directly towards or from the observer; but the following fundamental difference in the case of the two theories appears not to have been taken into account.

2. For the sake of precision we will take a special example. Suppose a luminous source with such an adjustment as to emit a parallel beam of light,[1] and let the luminous source be supposed put in motion in a direction at right angles to the path of the beam. Then on the basis of the corpuscular theory (according to which light consists of projected particles) since the particles or corpuscles, according to the laws of motion, partake necessarily of the motion of the body emitting them; so, therefore, if the corpuscular theory were true, the path of the emitted beam of light would be exactly the same in direction as if the luminous body were at rest. So, therefore, if we imagine a screen of the same breadth as the luminous beam to be placed at a distance, so that this screen is *exactly* illuminated when the luminous source is at rest, then (according to the corpuscular theory) this screen would also be *exactly* illuminated when both it and the luminous source were put in motion with equal velocities (in parallel paths) in the same direction.

3. This, however, will not be the case if the undulatory theory be true, for it is a known fact that waves emitted in a medium do not partake of the motion of the body emitting them. For when once a wave has left the body, the wave is dependent solely on the medium for its propagation and is not influenced by the motion of the body one way or the other. It follows, therefore, that in the case of a moving luminous source emitting waves transversely to its path, the waves forming the parallel beam will be left behind, or will not partake of the motion of the luminous source. The waves will form a slanting track of light which will no longer strike *exactly* the opposed distant screen, but will fall somewhat to the rear of it. The luminous beam which, when the screen and source were at rest, was exactly eclipsed or intercepted by the screen, will (when the screen and source are in motion) commence to escape behind the edge of the screen, or the eclipse will no longer be total.

4. Here, therefore, we should have in principle a simple and decisive test between the two theories, provided insuperable practical difficulties do not stand in the way of carrying it out (for which object probably various methods would suggest themselves).

In order to contrast further the different effects that would be produced in the case of the two theories (corpuscular and undulatory), we may consider various possible cases of relative motion, also the effect when the beam is received directly in a telescope, or in the eye. We have already considered the case where the beam is observed objectively (by the use of a screen), which we may call *Case I.*

5. *Case II.*—We may now consider the case when a telescope[2] is used. We will take the above example of a luminous source in motion, emitting a parallel beam of light at right angles to its path, and we will imagine that this beam is received in a distant *stationary* telescope, placed normal to the path of the moving luminous source, so that the beam flashes down the axis of the telescope at the instant of the passage of the luminous source. Then we have to compare the effects produced in the case of the undulatory and corpuscular theories. On the undulatory theory, waves emitted by a luminous source do not partake of the motion of the source, so that at the instant when the wave of the beam (singling out a particular wave) flashes down the axis of the telescope at the moment of passage of the luminous source, the source will have already moved on a distance from the point where the wave left it, this distance representing that traversed by it during the time the light took to pass from the source to the telescope; and the source is therefore seen out of its true position by precisely that amount. This is perfectly evident, and the correction for this error in the estimate of position (of the value above indicated) constitutes the well-known "equation of light."

6. We have now to consider what takes place on the corpuscular theory. Here the projected corpuscles will partake of the motion of the source. Singling out, therefore, one of the corpuscles that flashes down the axis of the telescope at the instant of the passage of the luminous source; this corpuscle will possess the transverse velocity of the source that emitted it, and therefore the corpuscle will not pass straight down the axis of the stationary telescope, but in its passage will deviate laterally from that axis. The telescope would accordingly have to be inclined in order that the corpuscle might pass along the axis. This deviation of the corpuscle from the axis of the telescope will cause the luminous source to be viewed out of its true position, and it is easily seen that this visual error in the estimate of the position of the source on the corpuscular theory is precisely the same in amount as the previous error (due to a different cause) on the undulatory theory. Indeed, the error on the corpuscular theory is simply a case of "aberration" due to the relative motion of the telescope and light), and the correction for it, according to known principles, is the same as the other correction on the undulatory theory, termed "equation of light.'" It is a remarkable fact, therefore, that though the path of the light in its transit is very different in the case of the two theories, the visual error in the estimate of the position of the object is the *same*, so that this error cannot itself serve as a test between the two theories. There is, however, one marked distinction between the two theories; for while on the undulatory theory a position of the telescope *normal* to the path of the moving luminous source, causes the flash of the beam to pass down the axis of the telescope; on the corpuscular theory, on the other hand, the telescope has to be *inclined* in order that the flash of the beam may pass down its axis. Here, therefore, we have a definite physical effect serving as a point of distinction between the two theories.

7. *Case III.*—We will now take the case when *both* the luminous source and the distant observer are in motion, moving with equal velocities in parallel paths alongside each other in the same direction. Here on the corpuscular theory, in which case the corpuscles partake of the motion of the source, since the whole system therefore moves with equal velocity, the whole system will therefore be *relatively* at rest; so that the light will pass across and enter the telescope just as it would have done if everything were at rest, or there will be no peculiarity in the passage of the light whatever on the corpuscular theory. It is widely different on the undulatory theory, for here the beam of light passing between the source and the telescope will be left behind in the medium, and therefore in the first place, the moving telescope, in order to catch the parallel beam, will have to be placed back a certain distance in the rear; for since the light takes a slanting track between the source and telescope (the degree of slant depending on their common velocity), the telescope to intercept the light, can no longer be placed exactly *opposite* the luminous source. The distance the telescope will require to be placed back evidently must be equal to that traversed by it during the time the light takes to pass from the source to the telescope. Secondly, the light on the undulatory theory will suffer aberration in passing along the tube of the telescope, owing to the latter being in motion relatively to the light; no such aberration taking place on the corpuscular theory, since the corpuscles are moving at the same velocity as the telescope. Thirdly, on the undulatory theory, there will be a correction necessary, due to the motion of the luminous source ("equation of light"); such correction not being required on the corpuscular theory, since on that theory the light emitted partakes of the motion of

[1] We consider a *parallel* beam of light for simplicity, though it is not necessary to the principle.

[2] Of course the effect produced by aberration is the same with the eye alone as with a telescope, but we prefer to consider the latter, as its larger scale enables the effect to be visualised better.

the source. But it is a curious fact that the two errors occurring on the undulatory theory ("aberration" and "equation of light") happen precisely to counteract each other; so that therefore the luminous source is seen in its *true* position, *i.e.*, in the *same* position as by the corpuscular theory. The fact of the two errors compensating each other therefore prevents this occurrence of error from serving as a visual test between the two theories. There is, however, a distinct objective difference between the two theories in this case, as regards the *position* of the telescope (previously referred to); but before recurring to this, we may consider more closely the mode in which the above compensation of the two errors is brought about.

8. It is well known that the effect of the error termed "aberration" is to make the luminous source appear *forwards* of the position it occupied when the wave left it, and this by an absolute amount equal to that traversed by the telescope during the time the light took to pass from the source to the telescope. But from the fact that the luminous source is in motion, the latter *is* actually at the time of observation situated *forwards* of the position it occupied when the wave left it, and by precisely the above amount (since the source is moving at the same velocity as the telescope). Hence the two errors will precisely compensate each other, and the luminous source will be seen through the telescope in its true position, *i.e.*, in the *same* position as by the corpuscular theory. But it is important to note that on the undulatory theory, the telescope, in order to receive the parallel beam emitted by the luminous source, must be placed *not* opposite the source, but somewhat backwards, to make up for the slanting track of the beam attendant on the motion of the luminous source. On the corpuscular theory, on the other hand (where the track of the beam of light is *normal* to the line of motion of the source), the telescope must be placed *opposite* the source in order to catch the beam. The *position* of the telescope in the two cases therefore constitutes a distinct physical difference between the two theories, which might serve as a test.[1]

9. The above considerations may suffice to show in a simple manner that important differences exist in the effects attendant on the motion of a luminous source on the corpuscular and undulatory theories of light, and that these differences would be *in principle* capable (supposing practical difficulties surmounted) of constituting a simple and decisive test between the two theories.

S. TOLVER PRESTON

[1] The fact pointed out by Sir John Herschel in regard to the difference in the *velocity* of light on the undulatory and corpuscular theories, in the case of a luminous body moving directly towards or from the observer, would appear also to be worthy of remark. It is evident, for example, that in the case of a luminous body moving towards the observer, the velocity of light would *add* itself to that of the body on the corpuscular theory; but the velocity would be unaffected on the undulatory theory.

GEOGRAPHICAL NOTES

THE Paris Geographical Society held last Friday its annual December meeting, at its hotel, under the presidency of Admiral La Roncière le Nourry. The report of the progress of geography was read by M. Maunoir, the secretary. M. de Ujfalvy delivered an address on the region of Central Asia which he visited, and which may be termed the extreme frontiers of the Russian empire, and which are just now attracting so much notice. This traveller will soon come to London to give the same address before the Royal Geographical Society. His exploration was made at the expense of the French Government. On the following Saturday a banquet took place at the Continental Hotel. The usual toasts were given. After dinner M. de Lesseps, who is very likely to be nominated president of the Society for 1879, at the April meeting, gave some account of his visit to Tunis with Capt. Roudaire, in order to investigate the conditions of the creation of the new Saharan Sea. M. de Lesseps described the whole scheme as being easily practicable for a sum of not more than 60,000,000 of francs. He said that the French extension telegraph system was extending all over Tunis and Tripoli, and that Arabs were accustomed to follow the telegraphic line as their camels travelled at a quicker rate when following its track. He intimated that the Egyptian telegraphic system was extending to the equator, and that he advised M. Cochery, the Director of French Postal Telegraphy, to extend it all over Sahara up to Senegal.

PETERMANN'S *Mittheilungen* (for so it will continue to be named) for December contains a long and careful account of Chartography at the Paris Exhibition; Dr. Carl Martin contributes a paper, based on Chilian sources, on the Chonos Archipelago, which is accompanied by a map. An excellent paper on the present condition of Afghanistan (with map), is contributed by Herr F. von Stein. This number, besides the usual table of contents to the volume, contains a complete alphabetically arranged index to Dr. Behm's useful monthly summaries.

WE have received a specimen of the first number of one of those stupendous geographical works of which the French are so fond, and the best example of which is Elisée Reclus' "Géographie Universelle." Indeed, the new work announced seems to have pretty much the same object as that of Reclus, though the method is different. The new work is to be issued by the Librarie des Connaissances Utiles, and the author is M. Charles Hertz. Its title is "La Géographie Contemporaine d'après les Voyageurs, les Émigrants, les Colons, les Commerçants." It will consist of ten series of from three to five volumes each. We trust the publishers will find subscribers patient enough to wait for the end. There will be from 600 to 800 maps and hundreds of illustrations, and the work will be issued in weekly parts. We calculate it will take fifteen years to complete. Judging from the specimen, a good deal of narrative and adventure will be introduced into the work, and that it will be at least as entertaining as instructive. The first series will deal with polar and maritime expeditions, the second with Africa, the third with Asia, the fourth with Australia, and the fifth with means of communication, geographical societies, &c. The other five series will be devoted to a description of the nations of European origin and their enterprises over the globe. It is a grand scheme.

DR. THOLOZAN, physician to the Shah of Persia, is organising a scientific exploration of the province of Khuzistan, the southern province of Persia. The expedition will start from Bassorah on February 1 next.

NOTES

THE Corporation of the City of London having determined to identify themselves with the movement by the Livery Companies of London for the advancement of technical education, on Thursday last elected the following to serve on the Board of Governors of "The City and Guilds of London Institute for the Advancement of Technical Education":—The Lord Mayor *ex officio*; the Recorder, *ex officio*; Aldermen: Sir Thomas Dakin, Knt.; Sir Robert W. Carden, Knt.; Mr. William Lawrence; Sir Francis W. Truscott, Knt.; Sir Wm. A. Rose, Knt., F.R.S.L., F.R.G.S.; Simeon C. Hadley; Common Council: Mr. Joseph Beck, F.R.A.S.; Mr. W. Bassingham; Mr. J. L. Shuter, F.R.A.S.; Sir C. Reed, Knt., LL.D., F.S.A., Dep.; Mr. George Shaw; Mr. J. Edmeston; H. Lowman Taylor, J.P., Dep.; S. E. Atkins, Dep.; Sir Jno. Bennett, Knt.; Mr. Henry Greene; Mr. John Faulkner; Mr. Thomas Waller.

Last week Dr. Gladstone read an important paper at the Society of Arts on science teaching in elementary schools. He assumed, first, that it is not good that poor children should go forth into the world in gross ignorance of the material objects among which they must always live and work; secondly, that it is far from desirable to try to make scientific men and women of boys and girls of twelve and thirteen years of age. "This earth," Dr. Gladstone said, "is our dwelling-place, from the cradle to the grave; our bodies are the complicated machines, so wonderfully made, by which every action of ours is performed; the sun, clouds, and atmosphere influence us every day; the animal, vegetable, and mineral kingdoms are ready to yield us their supplies; and the great mechanical and chemical forces, with heat, light, and electricity, are ready to be our servants if we do not allow them to become our masters. Every man, also, in his handicraft or trade, as well as every woman in her domestic duties, has to deal with some facts and objects of nature specially connected with them." Dr. Gladstone then proceeded to point out the present state of the question, showing that very much yet remains to be done ere science takes the place it ought to occupy in our elementary schools, though the energetic London School Board is doing much to give science-teaching an established place in the schools under their charge. He referred to the universality of science instruction in Germany, and expressed a hope that a "knowledge of common things" would soon take its place alongside of the older subjects in all our elementary schools.

We are glad to learn that the health of Prof. Hoffmann, the well-known chemist, is now completely restored, and that he is again among his pupils.

M. Flammarion writes to us in reference to a note from a correspondent last week, that the subscription he is organising is mainly for the purpose of founding at Paris a free observatory created by private means, on the model of those which exist in England. It is desired to establish in the observatory the most powerful instrument which the funds will enable to be constructed. This instrument is intended above all for the physical investigation of the planets, and particularly of the moon, "the vital state of which," M. Flammarion writes, "may thus be definitely settled. It is not proved," he says, "that the moon is a dead planet, but the progress of optics appears to me to be now such as to justify a serious investigation for traces of life upon it; in fine, to settle what opinion ought to be held on the question of the habitability of the moon."

The September number of the *Mineralogical Magazine and Journal of the Mineralogical Society of Great Britain and Ireland* contains three original papers. Mr. Sorby gives a few test-experiments of his new method of determining the refractive indices of mineral plates, which will hardly be new to readers of Nature. Prof. Heddle continues his papers on the geognosy of Scotland. The present one is almost entirely occupied with the geology of the Island of Fetlar, and gives several analyses of the minerals found in its different rocks. Prof. How's contribution to the mineralogy of Nova Scotia is mainly taken up with mordenite and some altered nodules found at Cape Split; the rest of the paper is not much more than a list of localities. Ten pages are taken up by very poor abstracts from the *Zeitschrift für Krystallographie* and other periodicals, which are far inferior to those published in some of the weekly journals. Most of these are by a gentleman who may be a mineralogist, but is scarcely a crystallographer. He is grandly impartial as to notation, apparently following the authors in using either the Millerian or Naumannian. When using the former he often forgets to state the system in which the mineral crystallises. When the latter is used in an English mineralogical journal, the least we can expect is to have the Millerian equivalents given side by side with the Naumannian symbols. The conversion is not difficult, and tables for the purpose are given in all the text-books. Near the end is an abstract by the editor of a flattering notice of his own book, the good taste of which is obvious. We find it difficult to think that a magazine so indifferently conducted can prove either a commercial or a scientific success.

Captain Howgate has sent us some of the results of the preliminary United States Arctic Expedition in the *Florence*, in the shape of reproductions of photographs and of drawings by the Eskimo. The latter are rude, but vigorous and amusing, and show the well-known talent of the natives for drawing.

Experiments on the electric light, with Jablochkoff candles, have been tried at Havre, and, in consequence of the frequency of maritime collisions, are attracting much notice from seamen. The *Breeze*, one of the British mail steamships, was stranded a few days ago, when trying to enter the Calais port, owing to the prevalence of fogs. This accident would not have taken place if an electric light had been placed at the end of the jetty, as had been proposed. It is said the matter has been reported to the French Minister of Public Works. The electric light experiments in the Avenue de l'Opera and in front of the Palais Legislatif are to be continued up to January 15, but at the expense of the company, the Municipal Council having refused to pay more than the sum which would have been spent by them if the streets had been lighted with ordinary gas.

The question of "reserves" for the aborigines having been recently raised in the Queensland Legislature, it has been recommended that the system of the Durundur reserve should be extended, as there are many other places where it might be advantageously tried.

We have received from Messrs. De la Rue several specimens of their diaries, which are marked by all their usual elegance and usefulness. Much valuable information is prefixed to several of the diaries, though we still regret the absence of some of the astronomical information which used to give them a distinctive value. Messrs. Letts have also sent us a number of their various forms of diaries, the marked feature of which is their utility. They are of all sizes and prices, and no one need have any difficulty in providing himself with this useful help to order and memory. Messrs. Letts have also published a handy weather table by Mr. Saxby, containing a great deal of useful and well-arranged information.

The *Madras Mail* states that great progress is being made in the cultivation of chinchona in the Wynaad, and that nearly a million plants have been taken there this year from the Neddiwuttum estates, and this is in addition to what is obtained from the extensive chinchona nurseries on all the coffee estates. All the poorer parts of these are being planted with chinchona which is found to thrive well where coffee will not grow.

A letter from Peking states that the Viceroy Li Hungchang has entered into a contract with Mr. Arnold Hague, of New York, an able geologist and mining expert, for the purpose of prospecting the gold, silver, and other mines in the north of China. Mr. Hague is expected to start shortly from Tientsin for the mining regions. The just published Consular Report from Canton also states that General Fang, a well-known military officer, has been instructed to arrange for an immediate supply of European machinery to be used in local mines. It appears to be thought that there is great likelihood of the early working of coal and other mines in the provinces of Chihli, Kiangsi, Kiangsu, and Szechuen.

For some time past there has been so little water in portions of the Grand Canal of China, that it has only been navigable by

small boats, and for this reason, among others, it has been found necessary to send the grain tribute up to Peking by sea. The last mail from China, however, brings news of an unusual rise in its waters. A correspondent of the *North China Herald* left Tientsin on October 10 and observed no especial increase in the water until he reached the town of Hsingchi, about seventy miles to the south. There he met with a south-west wind, and noticed the water up to the top of the banks. Further on the people were seen raising narrow ridges to prevent the water from overflowing into the fields. Beyond the city of Tsingchow, and as far as the Narpi district, large tracts of land were under water. The general level of the country east of the canal is about six or eight feet below the artificial embankment, and in not a few places this is very weak from the constant wash, especially at the bends, so that the danger is serious. The writer had not been able to learn the cause of this unusual and rapid rise in the Grand Canal, but the Chinese attribute it to heavy rains in the mountainous region to the south-west, though it has never been known to happen before so late in the year.

THE Board of Trade having received, through the Foreign Office, reports from Her Majesty's Consul at Taganrog as to the recent destruction of corn crops in the neighbourhood of that place by a beetle described as the *Anisoplia austriaca*, have communicated with the Entomological Society of London, and have been favoured by that Society with a report upon the subject. The Report is signed by Messrs. McLachlan and Waterhouse, who state that the insect *Anisoplia austriaca* has nothing whatever to do with the "Colorado beetle." It belongs to a group of beetles (Rutelidæ) allied to our common cockchafer, but is of very much smaller size. There can be no doubt, they state, that the eggs are deposited in the earth at the roots of corn and grasses, that they soon hatch, and that the larva feeds upon the roots. How long a period elapses before the pupal state is assumed they know not, but they think that two years may be the outside limit, and that in the autumn of the second year of its existence, the larva either forms a cocoon in which it remains quiescent until the following spring, when it assumes the pupal state, or, as is more probable, it assumes that state in the autumn, and the perfect insect may be developed soon afterwards, but remain in the cocoon until the following summer. All accounts, however, they have been able to refer to concerning this and congeneric species, agree (as does the information furnished by Mr. Carruthers) in attributing the chief damage to the perfect insect, which feeds upon the green corn in the ear. After referring to the abundance of the beetle in some parts of Germany, they commend, as a preventive of its ravishes, rotation of crop and encouragement of insectivorous birds, and state their opinion that there is no reason to apprehend the recurrence year after year of such multitudes of the beetles as have occasionally appeared. "In the present state of entomological science," they conclude, "it is impossible to accurately account for visitations like this, which occur with many insects, injurious or otherwise. It may be that the pupal condition is prolonged indefinitely, or until circumstances favour its determination; by this reasoning (which is warranted by what we know to be the case in some other insects) the pupæ might be accumulated from year to year, and the perfect insects from these accumulations burst forth simultaneously."

AT the second monthly meeting of the Statistical Society, held on the 17th inst., Dr. Mouat, Foreign Secretary of the Society, who was deputed to represent it at the meetings in Paris of the Demographic Congress, and of the Permanent Commission of the International Statistical Congress, and, in Stockholm, of the International Penitentiary Congress, read reports of the proceedings of those bodies, so far as they were of interest to the Statistical Society. The chief work of the Permanent Commission was its own reorganisation as the executive of the Statistical Congress, and the adoption of a scientific scheme of classification of statistics for international purposes. Statistical annuals for 1877 have been published in France, Italy, Prussia, Austria, Hungary, and Belgium, all differently arranged. With a view to the adoption of uniformity of system on strictly scientific principles, M. Deloche, the chief of the General Statistical Department in Paris, suggested such a system, and it was adopted. Taking territory and population as its basis, the subsequent grouping of the many and varied facts by which human activity is manifested was in the order of the faculties to which they naturally attach themselves, viz., the moral, the intellectual, and the physical. Reference was made by Dr. Mouat to the large amount of valuable statistical information collected and published annually in the form of the statistical abstracts of the British Empire; and to the mass of miscellaneous statistics furnished from time to time to Parliament. Dr. Mouat was of opinion that the time had not yet arrived for the scientific classification of statistics, and he suggested for consideration a more simple form under four heads, viz., (1) Territory and Population; (2) Revenue and Commerce; (3) Laws and Government; and (4) Miscellaneous Statistics, containing all that cannot be grouped under any of those heads. The Demographic Congress was entirely devoted to the consideration of questions of population in the aggregate, or the natural history of society, as distinguished from physiology—births, deaths, marriages, migrations, &c.

THE *Times* a few weeks ago gave prominence to some facts showing the highly electrical condition of the atmosphere in Canada during the fine dry winter there. A letter from Mr. A. H. McNab, of Teignmouth, in the *Western Times* of December 17, will show that similar conditions exist in England during similar weather. He says:—"About 7.45 P.M. on Friday I was crossing Shaldon Bridge from the Teignmouth side, and immediately after passing the 'drawbridge' I was much surprised to find both sides of the bridge illuminated at certain regular distances with pale blueish lights resembling flickering lamps. My first impression was that, owing to the dense fog that prevailed, some sort of lamps had been placed on the bridge as a warning for the boats and barges passing up and down the river, but on coming to the first iron upright in the bridge railing I at once came to the conclusion that the light was electrical, for each point of iron had a flame of about two inches in height, composed of electric sparks issuing from it, accompanied by a hissing sound resembling that caused by the escape of gas from unlighted burners, and all the iron points along the bridge were similarly illuminated, producing a most charming effect. The point of the umbrella which I carried was also emitting a light, and when moved about produced sparks and sound. When I was midway across the bridge a passenger suddenly appeared in the fog and called out to me, 'Sir, your umbrella has a light on the end of it.' His surprise, however, was not lessened when I informed him that his own umbrella had the same. So far as I observed the phenomenon was entirely confined to the bridge, and on my return some time after it had entirely disappeared. Perhaps the large amount of iron in the bridge may have something to do with it."

THE mission of Sergeant Jennings, of the United States Signal Corps, has not been quite fruitless in Paris. A sort of weather indicator has been placed, by order of the Prefect of the Seine, at the doors of the Luxembourg Palace; others will, it is said, be very shortly installed in several places of Paris.

AS No. 1 of "Dimmock's Special Bibliography" (Cambridge, Mass.) we have received a descriptive list, arranged according to date, of the Entomological Writings of Prof. John L. Le Conte, compiled by Mr. S. Henshaw. There are 150 entries, and the list seems compiled with great care and must prove useful to entomologists.

ABSORPTION OF WATER BY THE LEAVES OF PLANTS

THE experiments of Boussingault, referred to in NATURE, vol. xviii. p. 672, find a fitting sequel in those of the Rev. G. Henslow, detailed in a paper read before the Linnean Society on November 7. Although gardeners universally maintain that growing plants have the power of absorbing water through their leaves, both in the liquid and the gaseous form, in addition to the power of suction through the roots, yet the contrary theory has been in favour during recent years among vegetable physiologists. The first recorded experiments of any value on the subject were about the year 1727, by Hales,[1] as described in his "Statical Essays;" the conclusion to which he came being that "it is very probable that rain and dew are imbibed by vegetables, especially in dry seasons." This result was confirmed by Bonnet in 1753. A century later, however, in 1857, Duchartre, experimenting on the absorptive power of plants, came, after considerable wavering, to the conclusion that rain and dew are not absorbed by the leaves of plants. This opinion has been, with but little exception, held by all physiologists during the last twenty years, notably by De Candolle and Sachs; the explanation offered of the fact that withered plants revive when placed in moist air or when the leaves are moistened, being that transpiration is thus stopped, or is more than counterbalanced by the root-absorption. In his "Text-book of Botany" (English edition, p. 613), Sachs says:—"When land-plants wither on a hot day, and revive again in the evening, this is the result of diminished transpiration with the decrease of temperature and increase of the moisture in the air in the evening, the activity of the roots continuing; not of any absorption of aqueous vapour or dew through the leaves. Rain again revives withered plants, not by penetrating the leaves, but by moistening them, and thus hindering further transpiration, and conveying water to the roots, which they then conduct to the leaves." McNab has, however, proved that leaves do transpire, even in a moist atmosphere, provided they are exposed to the action of light.

The results of Mr. Henslow's experiments, extending over several years, are altogether in accordance with those of Boussingault, and may be considered to set the question of the absorbent power of the leaves of plants completely at rest. The following are the chief conclusions arrived at:—1. The absorption of water by internodes. The experiment consisted of wrapping up one or more internodes of herbaceous plants in saturated blotting-paper and in noticing the effects. As a rule the leaves on the shoots rapidly perished, showing that transpiration was too great for the supply. The stems, however, kept fresh for different periods up to six weeks. 2. Absorption by leaves, to see how far they could balance transpiration in others on the same shoot. The general result is that as long as the leaves remain green and fresh in or on water, they act as absorbents, but that the leaves in air keep fresh or wither according as the supply equals or falls short of the demand. 3. To test how far leaves on a shoot can nourish lower ones on the same shoot. It appears that it is quite immaterial to plants whether they be supplied from water by the absorbing leaves being above or below those transpiring. Water flows in either direction equally well. 4. Leaves floating on water. It was found that one part of a leaf can nourish another part for various periods, though the edges out of water died first. 5. Absorption of dew. A long series of cut leaves and shoots were gathered at 4 P.M., then exposed to sun and wind for three hours, then carefully weighed and exposed all night to dew. At 7.30 A.M., after having been dried, they were weighed again, and all had gained weight and quite recovered their freshness, proving that slightly wetted detached portions do absorb dew. 6. Imitation dew. Like results followed from using the "spray," by which dew could be exactly imitated. 7. Plants growing in pots and of which the earth was not watered, were kept alive by the ends of one or more shoots being placed in water; *e.g.*, *Mimulus moschatus* not only grew vigorously and developed axillary buds into shoots, but even blossomed.

By these interesting experiments the physiological botanist is again placed in harmony with the gardener who syringes his plants, not merely for the purpose of washing off dust and insects, but in order to facilitate the actual absorption of water by the surface; and with the field botanist, who sprinkles the plants in his vasculum with water to keep them fresh till he reaches home. The fact which now seems established beyond all doubt by the observations of Darwin and others, that certain plants have the power of absorbing through their leaves and digesting the remains of animal substances, also implies, as a necessary corollary, the absorbent power of leaves for certain liquid or gaseous substances. In connection with this subject sufficient attention has perhaps not been attracted to the observations of Prof. Calderon, as detailed in a paper printed at Madrid, in English (1877), entitled, "Considerations on Vegetable Nutrition."[1] Calderon's statements—which, however, require at present to be confirmed by other observers—are to the effect that plants have the power of absorbing the nitrogenous organic matter which is constantly floating in the air, and that, if air be deprived of all organic matter, it is unable to sustain vegetable life, all the physiological functions of plants being then suspended.

A. W. B.

[1] In his "Geschichte der Botanik," pp. 515-521, Sachs gives an admirable epitome of the great service rendered to the progress of botanical science by the researches of this eminent botanist and physicist.

[1] See NATURE, vol. xv. p. 108.

UNDERTONES

THESE formed the subject of a lecture delivered by Herr Auerbach before the meeting of Naturalists at Cassel this year.

The term "undertones," he pointed out, is an extension of the nomenclature which denotes certain accompanying tones of a given note "overtones." Undertones may be observed in the following way:—If a struck tuning-fork be set on a sound-board, a tone is heard sounding strongly, which before was little perceptible. The stem of the fork makes longitudinal vibrations, which, by action on the sounding-board (a very thin one), generate transverse vibrations, and these spread over the large surface of the plate. Should the tone of the board only differ in intensity from that of the fork, the vibrations executed by the stem of the tuning-fork must be small; it is otherwise, however, when the vibrations exceed a certain amount.

Herr Auerbach demonstrated his observation with a tuning-fork giving the A of a violin, and so 435 vibrations per second. When he placed the vibrating fork firmly on a sonud-board, the tone was heard distinctly at a distance. When, however, he brought the tuning-fork, struck very vigorously, into very light contact with the plate, there was heard the lower octave of the fork's tone. With other materials, which were not then at his command, he could produce also the lower fifth of the lower octave, and the lower fourth of this tone, *i.e.*, the double octave of the fork's tone. The vibration numbers of these resonance tones are $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, &c., of that of the tuning-fork's tone, *i.e.*, the resonance-tones form the series of the *harmonic undertones*.

With regard to the mode of occurrence of these tones, Herr Auerbach said this: "To prove to you, first of all, that the strength of the vibrations is the fundamental condition of the phenomenon, I will once more make the experiment, and continue it longer. You heard first, again, the lower octave; but then the tone sprang over into the higher, so that it became identical with the proper tone of the tuning-fork. Consider this result along with the fact that the vibrations of the fork rapidly diminish; remember, too, that it is only when the fork is vigorously struck and lightly placed on the plate that the undertones occur, and you will see that the cause of the phenomenon lies in the amplitude of the vibrations."

Herr Auerbach further supposes that the resonance-surface of the plate, being imperfectly elastic, follows the movements of the stem of the fork immediately downwards indeed, but not upwards; an interval then occurs which only disappears on the next passage downwards of the stem. If the retardation be a small one, the plate, at the moment of meeting the stem a second time, has nearly completed a vibration. If, however, the retardation be great, the undertones arise (as the lecturer showed graphically) from the combination of the vibrations of the stem and the plate. The stem-end, *i.e.*, in this latter case, is no longer an unconditionally free end, but its freedom is a periodic function of the time, and this period is twice as great as that of the tuning-fork vibrations. "That the undertones arise in consequence of internal friction, was easy to see *à priori*: what the experiments have shown and explained is the interesting fact, that precisely the *harmonic undertones* are produced; that is a consequence of the fact that the resonance is the action of a periodic force, and so, in a certain sense, a discontinuous phenomenon, otherwise the undertones must form a continuous series, which is not the case."

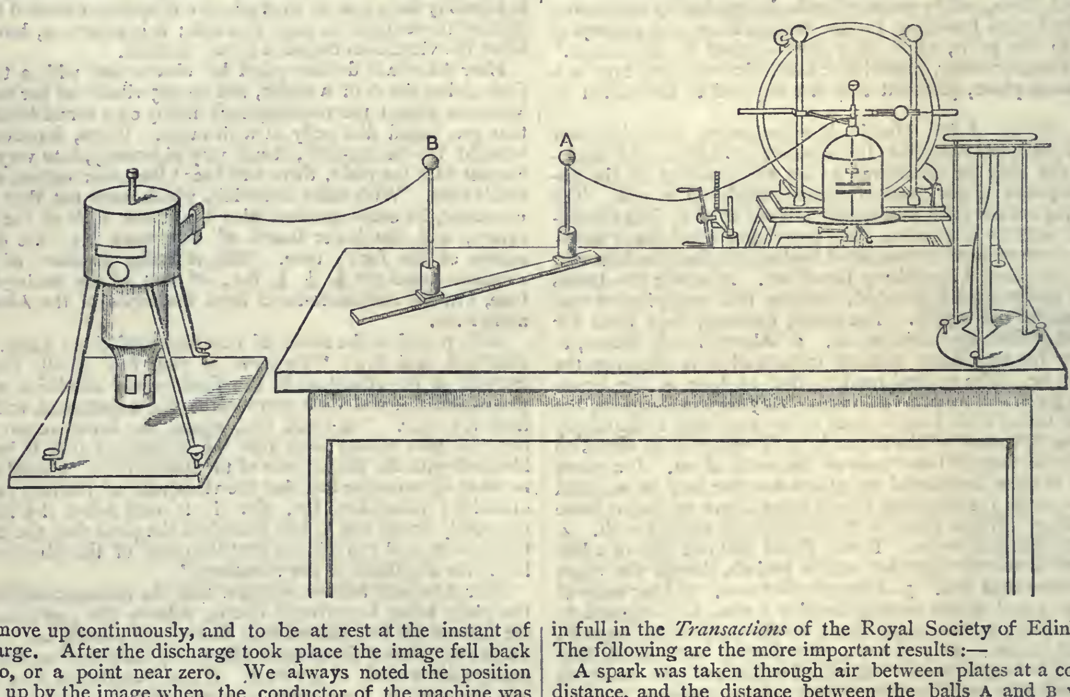
"It is obvious," he continues, "that the description given of the phenomenon is incomplete, for ductility, elasticity, variation of the resonance-plate, &c., co-operate to produce a more complicated phenomenon. I have tried a great many materials for undertones, and found that they fall, in this respect, into three groups. In the middle stand those materials which furnish undertones, that is, the great majority of all substances in general. On the one side are those substances which, as soon as the vibrations are pretty strong, give no resonance-tones, but merely an indeterminate noise; to this group belong rolled plate metal and most kinds of glass. On the other side are those substances which, however strong the vibrations, always give the tone of the tuning-fork. I have found only one example of this, viz., the wood of mountain fir, in thin polished plates. It was natural to try the belly of a violin, which is mostly made of fir-wood, for undertones, and in this way form an idea as to the elasticity of the wood, on which the excellence of the instrument greatly depends. From the German violins I have examined, I have always obtained undertones; from the few authentic Italian violins accessible to me I obtained, on the other hand, always the original tone. But I acknowledge that more abundant material is necessary for a decision of this question."

THE DISRUPTIVE DISCHARGE OF ELECTRICITY[1]

BY means of the following method we have been able to investigate the laws of the disruptive discharge of electricity of high potential—a subject of investigation which is the complement of that in which Drs. Warren de la Rue and Müller have been simultaneously engaged. In making these experiments I have had the able co-operation in succession of Messrs. Salvesen, Connor, Stewart, Simpson, and Playfair.

The method essentially consists in connecting the prime conductor of the Holtz machine, not with the electrometer directly, but with an insulated spherical ball placed at some distance from an equal spherical ball, the latter being connected with the electrometer. The woodcut represents, *in situ*, the apparatus which was used in the case of the gases. The receiver of the air-pump, which has a rod capable of moving air-tight, was attached to one of the conductors of the Holtz machine in such a manner that the conductor and the rod formed one conducting system. Projecting from the plate of the air-pump was a short metal rod, which formed one conductor with the metallic parts of the air-pump, and, by means of a wire, with the uninsulated conductor of the Holtz machine. Electrodes of various forms were made to screw on to the ends of the rods. Of the two insulated brass balls one, A, was fixed; the other, B, could be moved along the connecting board. The wire joining A to the collar of the receiver is insulated with gutta-percha. The electrometer in connection with B is one of Sir W. Thomson's divided ring reflecting electrometers.

When the potential of A is raised by driving the machine, the potential of B is also raised, and this goes on until a discharge takes place between the electrodes inside the receiver. Hence the maximum deflection of the spot of light from zero is an indication of the difference of potential of the two surfaces between which the spark passed immediately before the discharge. By breaking the contact between the conductors of the Holtz machine before beginning to turn the wheel, and, by turning slowly and uniformly, we were able to make the image of the



wire move up continuously, and to be at rest at the instant of discharge. After the discharge took place the image fell back to zero, or a point near zero. We always noted the position taken up by the image when the conductor of the machine was completely discharged.

The force resisting the deflection of the mirror is the action of two external magnets upon several small magnets fixed to the back of the mirror.[2]

One great merit of our method is the rapidity with which observations can be made. Three readings were in general taken for each entry. The mean of these is very probably free from any error due to accidental variations in the passage of the spark. An extensive series of observations have been printed in full in the *Transactions* of the Royal Society of Edinburgh. The following are the more important results:—

A spark was taken through air between plates at a constant distance, and the distance between the balls A and B varied. Let V denote the induced potential, and r the distance between the centres of A and B; then the experimental curve obtained satisfies the equation—

$$V = 6081r^{-1} - 42{\cdot}26$$

for values of r greater than 24 centimetres; but for less values of r the function requires to be corrected by being multiplied by—

$$\cdot524 + \cdot02r.$$

Sparks were taken through air at the atmospheric pressure between parallel metal disks of 4 inches diameter for distances up to 1·2 centimetres. The function for V, the difference of potential in terms of s, the length of the spark is—

$$V = 66{\cdot}94\sqrt{\{s^2 + \cdot205s\}},$$

[1] Abstract by the author of thesis for D.Sc. and other papers printed in the recently issued part of the *Transactions* of the Royal Society of Edinburgh. By Alexander Macfarlane, M.A., D.Sc.

[2] Our results were reduced to absolute measure by means of the absolute electrometer represented on the table.

the equation of a hyperbola whose semi-transverse axis is ·1025 centimetres, and semi-conjugate axis 6·8623 C.G.S. units. From the above equation we infer that—

$$R = 66·94 \sqrt{\left\{1 + ·205 \frac{1}{s}\right\}}$$

where R denotes the electrostatic force; from which it is evident that as s becomes smaller R becomes greater. A similar curve was obtained when hydrogen was substituted for air.

When the disks were heated before taking the sparks, the curve obtained satisfies the equation—

$$V = 87·04s - 19·56s^2,$$

a parabola, from which we deduce—

$$R = 87·04 - 19·56s.$$

It was found that when the capacity of the charged conductor was changed, the difference of potential required to produce a spark remained constant.

When the discharge was continued so as to keep the spot of light at a fixed deflection, the reading was always less than for the corresponding single discharge, but the curves were similar.

Readings were taken of the difference of potential required to produce a ·5 centimetre spark through air at different pressures from the atmospheric to 20 mm. They give—

$$V = ·0458 \sqrt{\left\{p^2 + 203p\right\}}$$

where p denotes the pressure in millimetres of mercury.

The electric strengths of several gases were determined by comparing the differences of potential required to pass a ·5 centimetre spark through the gas at the atmospheric pressure.

Dielectric.	Electric Strength.		
	Macfarlane.	De la Rue and Müller.	Faraday.
Air...	1	1	1
Carbonic Acid ...	·95	1·06	·91
Oxygen	·93	1	·71
Hydrogen... ...	·63	·54	·53
Coal Gas	·93	—	·71

"Electric strength" is the term used by Prof. Clerk-Maxwell to denote the physical constant in question. I have added, for the sake of comparison, values deduced from the results of De la Rue and Müller and of Faraday, but the ratios given do not strictly give the relative electric strength, but the ratio of the lengths of spark when the difference of potential is kept constant.

The difference of potential required to produce a spark between two spherical balls is approximately proportional to the square root of the length of the spark. This we have verified up to 15 cm.

On proceeding to investigate the discharge through insulating liquids, we first took up oil of turpentine. The liquid was placed in a glass jar of 7 inches diameter and 5 inches height. A screw passing through the bottom of the jar served to fix the lower electrode, and also to afford conducting connection with the earth. We observed four modes of discharge: by means of threads of solid particles, by motion of the liquid, by a disruptive discharge, and by motion of gas bubbles. When a chain was formed the index of the electrometer behaved as if a current were passing. The discharge, when sufficiently great, broke the thread and turned into a spark. The liquid was more easily set in motion when its surface was not much higher than the upper plate. The bubbles of gas appeared to be formed by the passing of the spark. They were always attracted to the negative electrode. When the electrification was neutralised they of course adhered to the under surface of the upper disk; when the disk was electrified negatively they still adhered; when positively they were repelled so as as to remain suspended in the liquid or to adhere to the lower electrode, according to the greater or less distance between the electrodes. At a diminished pressure the bubbles produced at the upper surface were observed to effect the discharge by carrying the electricity with them to the negative electrode. The fact that it is possible to cause a shower of electrified bubbles to descend and produce a flash and sound on impinging on the lower surface appears to throw some light upon the nature of lightning balls.

Similar phenomena were observed in paraffin oil, excepting that the gas bubbles produced were generally attracted to the positive surface.

We observed the differences of potential required to pass a spark through paraffin oil and oil of turpentine between plates for distances up to ·5 cm. It was impossible to observe for greater distances, as our insulated wire allowed the charge to escape. For paraffin oil,

$$V = 750\,s - 15;$$

therefore, $R = 750.$

The above has not been reduced to absolute measure. Thus R is constant in the case of the liquids, but variable in the case of the gases.

Electric Strength of Liquid Dielectrics

Air	1
Paraffin Oil (kind used for burning)	4
Oil of Turpentine	3·7

Sparks were taken between two platinum wires placed at right angles to one another. When one of the wires was heated by a voltaic current the electrometer deflection was diminished by about one-fourth of its amount.

We have also investigated the effect upon the electric spark of heating the air round the disks, the pressure being kept constant. The deflections of the electrometer for a constant spark for temperatures from 20° C. to 280° C. indicate a curve which slopes down gradually as the temperature is increased, while the deflections during cooling give a curve which is somewhat lower at the lower temperatures.

These experiments were made in Prof. Tait's laboratory, to whom we are indebted, not only for the use of apparatus, but also for ever ready advice.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 10.—The loss of electricity by an insulated charged body in rarefied gas in an envelope that has conductive connection with the earth is here stated by Herr Narr to be due to two processes distinct in time and intensity, the first, one of outflow, rapid and intense, the other, one of dispersion, slow and weak. The intensity of the former increases with decreasing density of each of the gases used (CO_2 air and H), and also on substituting one gas for the other in the order just given, the density remaining constant. These differences between the gases decrease with the density, and in vacuum fal within the limits of errors of observation. In discussing these results, Herr Narr is led to regard the condensed layer of gas on the conducting system as an insulator, not as a conductor.—Dr. Holz finds that the specific magnetism of magnetic ironstone is the greatest of all magnetic substances hitherto examined. Its maximum permanent magnetism is nearly as great, and partly greater than that of steel as hard as glass. Its permanent magnetism is sooner removed in demagnetisation with the same external forces than that of steel, &c.—Dr. Strouhal enunciates the laws of a mode of sound-production not much studied hitherto, that, viz., of rapid swinging of a rod, a blade, or the like, in air, or the passage of air-currents over strong wires or sharp edges, &c. —Herr Braun contributes a long and interesting paper on the development of electricity as equivalent of chemical processes.—Herr Koch demonstrates the applicability of the method of determining coefficients of elasticity from the bending of short bars supported at the two ends, the sinking in the middle being measured by means of Newton's interference-bands, and he suggests a more thorough investigation of the elasticity of crystals, by the improved means he describes.—Some remarks on the atomic weight of antimony, with reference to Cooke's recent research, are communicated by Herr Schneider.

American Journal of Science and Arts, November.—In the opening paper Prof. Dana considers the value of some distinctive characters generally accepted in defining certain kinds of rocks, as, "older and younger," foliated or not, and porphyritic structure; showing them to be often trivial and inapplicable. —With regard to the relative agency of glaciers and sub-glacial streams in the erosion of valleys, Prof. Miles considers that the streams are of primary importance in working in advance of the ice in deepening and enlarging these valleys, and that the glaciers abrade, modify, and reduce the prominent portions left by the streams, and give them the well-known glaciated sur-

faces.—Prof. Holden describes certain cloud-shaped forms (obscuring the smaller forms of Janssen) observed on the sun's disc on September 16, and cites a like observation made by Prof. Langley, in 1873, who thinks the effect chiefly due to our own atmosphere, while disposed to admit the possibility of some obscuration in the sun itself.—A pseudomorph after anorthite, from Franklin, New Jersey, is described by Prof. Roepper; and Prof. Verrill gives an account of recent additions to marine fauna of the east coast of North America.—There is also a notice of Edison's sonorous voltameter.—Prof. Marsh's important contribution on the principal characters of American Jurassic dinosaurs has been previously referred to in these columns.

Sorokin.—The development of the knee-joint in man, with remarks on the joints in general, and the knee-joints of vertebrates, by A. Bernays.—The skeleton of the Alcyonaria, by G. von Koch, including a minute description of the skeleton in each genus, a general account of it, and a new systematic arrangement, 33 pages, with 2 plates.—C. Hasse continues his studies on fossil vertebræ; this part is devoted to their histology, and is illustrated by 4 plates.

Zeitschrift für wissenschaftliche Zoologie, vol. xxxi. Part 2.—Contribution on the Julidæ, by E. Voges, dealing very considerably with the tracheal system and its development. There are descriptions of many new species of Julus, Spirostreptus, and Spirobolus; 68 pages, 3 plates.—On the development of the blastoderm and the germinal layers in insects, by N. Bobretzky, with figures chiefly of *Porthesia chrysorrhœa*.—On the genus Brisinga, by H. Ludwig.—On Aspidura, a mesozoic genus of ophiurid, by Hans Pohlig.—On the structure and development of sponges, Part 5, by F. E. Schulze; another most valuable contribution, the author having now completely followed the development of *Sycandra raphanus*, 34 pages, with 2 beautiful plates.

Parts 3 and 4 in one.—On the cerebral sulci in Ungulata, by Julius Krueg; the paper deals very largely with the fœtal development of the convolutions, 50 pages, 4 plates.—Contributions to the anatomy of Ophiurans, by Hubert Ludwig, treating especially on the skeleton of arm and mouth, and the sexual organs, 50 pages, 4 plates.—On the generative organs of *Asterina gibbosa*, by Hubert Ludwig, 1 plate.—An account of the anatomy of Magelona, an interesting form, by Dr. W. C. McIntosh, of St. Andrews; translated from English for the journal, 72 pages, 10 plates.—On some cases of parasitism among Infusoria, by J. van Rees.—Brief notes on the development of Anodon, by C. Schierholz.

SOCIETIES AND ACADEMIES

London

Royal Society, December 12.—"The Magic Mirror of Japan," Part 1, by Professors W. E. Ayrton and John Perry, the Imperial College of Engineering, Japan. Communicated by William Spottiswoode, M.A., Treas. R.S., &c.

The President stated that Prof. Ayrton had agreed to give, in the Friday evening discourse on January 24, at the Royal Institution, a full account of Japanese mirrors, so that on the present occasion he understood the authors of the paper merely proposed to enter very shortly into the subject.

Prof. Ayrton commenced by remarking that mirrors in Japan held a very high position, and constituted the most prominent feature in the Japanese temples, taking the place of the cross in Roman Catholic countries, and that the principal mirror in the Imperial Palace ranked higher than even the Emperor himself. He referred to the important place the mirror held in the very limited furniture of a Japanese household; to the respect attached to it by the women, and to the fact that while the sword was considered as "the soul of the samurai" (or two-sworded class) the mirror was looked on as "the soul of the woman." He next showed experimentally the so-called magic property possessed by certain rare bronze mirrors, sold by the Chinese at about twenty times the cost of the ordinary mirrors of that country, and which consisted in these mirrors being able to reflect from their smooth polished faces the raised patterns of birds, flowers, dragons, or Chinese letters with which their backs were adorned. He stated that he had found this property to be possessed by a very small percentage of the Japanese mirrors which he had experimented on, but that its existence was quite unknown to the people of that country. The phenomenon had been known in China for centuries, and that, therefore, while he showed it experimentally to the Fellows, he did so in case there might be some there who had never seen it, in consequence of these magic mirrors being rare; but he desired it to be remembered that it was not the phenomenon itself but the explanation of it which he had the honour of bringing before them as new.

After citing all the possible ways in which this curious reflecting power could be accounted for, and referring to a number of printed notices that had at various times appeared of the magic mirror, the majority of which were accompanied with a theoretical explanation, he remarked that as the authors had apparently not made direct experiments with the mirror itself to elucidate the cause of the phenomenon, but rather to have satisfied themselves with endeavouring to find out how it could be reproduced in Europe, it was not to be wondered at that many of the suggested possible explanations were very far from the truth. Up to the present time, he believed, the idea of inequality of density of the surface of the metal mirror produced naturally in cooling, or in the supposed process of stamping, seemed to have found most favour in the West, while the belief that this variation in density arose from trickery on the part of the maker was the view entertained in China. Sir David Brewster and Sir Charles Wheatstone, on the other hand, who also thought that trickery was the explanation, believed the artifice to consist in the maker skilfully scratching on the face of the mirror, before polishing, lines exactly corresponding with the pattern on the back.

Prof. Ayrton next described what was the explanation of the phenomenon his experiments, made during the winter of 1877–78, had led him to, viz., that there existed extremely slight irregularities in the curvature of the polished surface (quite invisible to direct vision), of such a nature that the thicker parts, corresponding, of course, with the raised patterns on the back, were flatter than the remaining convex surface, so that there was less dispersion of light from the thick portion than from the thinner. He then described one of a series of diagrams illustrating various experimental arrangements of convergent and divergent beams of light which the authors had availed themselves of, and the use of which constituted, he said, the essence of the system of investigation employed by Prof. Perry and himself, and he explained that if his theory of the phenomenon was correct, then placing the screen, on which the reflection of the light from the Japanese mirror was cast, in a certain position, the phenomenon ought to *disappear*, and again putting the screen in another position, the phenomenon ought to be *inverted*; that is, instead of a bright image on a dark ground, which hitherto had alone been what has been observed by previous investigators, a dark image of the pattern on a bright ground ought to appear. This disappearance and absolute inversion of the phenomenon he said he had found to actually take place, but that he was compelled from want of time to leave the experimental exhibition of it for the Royal Institution. Various other facts, such as the necessity of holding the screen rather near, but not very near, the mirror when ordinary sunlight without lenses was employed, was, like the inversion phenomenon just referred to, shown to be explainable only on the inequality of curvature theory, and not on the inequality of density theory.

The next question that arose was how was this inequality of curvature produced? This was explained to be due to the method employed by the Japanese for making the face of the mirrors convex, which method had hitherto been quite unknown to foreigners, but which Prof. Ayrton had, after much trouble, found to consist in scratching the face while cold with a *megebo*, or "distorting rod." During the operation the mirrors became visibly concave, but, receiving a "buckle," sprung back again so as to become convex when the pressure of the rod was removed. The thicker parts of these magic mirrors yielded less under the pressure, were made therefore less concave when under the rod, and sprung back less, or became less convex, when the pressure of the rod had been removed. He then showed how this explained the fact discovered by Prof. Atkinson, of the Imperial University, Japan, in 1877, that a small scratch made on the back of a mirror with a blunt nail, although producing apparently no effect on the other side, became nevertheless visible as a bright line on the screen when a light was reflected from the mirror.

Prof. Ayrton concluded by remarking that while the Japanese knew nothing of the so-called magic phenomenon that formed the subject of the paper that evening, he had ascertained that

they had used another property for their priestcraft, but the account of this he would reserve for the lecture at the Royal Institution.

"On the Torsional Strain which remains in a Glass Fibre after Release from Twisting Stress," by J. Hopkinson, D.Sc., F.R.S. It has long been known that if a wire of metal or fibre of glass be for a time twisted, and be then released, it will not at once return to its initial position, but will exhibit a gradually decreasing torsion in the direction of the impressed twist. The best method of approximating to an expression of the facts has been given by Boltzmann ("Akad. der Wissensch. zu Wien," 1874). He rests his theory upon the assumption that a stress acting for a short time will leave after it has ceased a strain which decreases in amount as time elapses, and that the principle of superposition is applicable to these strains, that is to say, that we may add the after-effects of stresses, whether simultaneous or successive. Boltzmann also finds that, if $\phi(t)\tau$ be the strain at time t resulting from a twist lasting a very short time τ, at time $t = 0$, $\phi(t) = \frac{A}{t}$, where A is constant for moderate values of t, but decreases when t is very large or very small. A year ago I made a few experiments on a glass fibre, which showed a deviation from Boltzmann's law.

The glass fibre examined was about 20 inches in length. The glass from which it was drawn was composed of silica, soda, and lime—in fact, was glass No. 1 of my paper on "Residual Change of the Leyden Jar" (*Phil. Trans.*, 1877). In all cases the twist given was one complete revolution. The deflection at any time was determined by the position on a scale of the image of a wire before a lamp, formed by reflection from a light concave mirror, as in Sir W. Thomson's galvanometers and quadrant electrometer. The extremities of the fibre were held in clamps of cork; in the first attempts the upper clamp was not disturbed during the experiment, and the upper extremity of the fibre was assumed to be fixed; the mirror also was attached to the lower clamp. This arrangement was unsatisfactory, as one could not be certain that a part of the observed after-effect was not due to the fibre twisting within the clamps and then sticking. The difficulty was easily avoided by employing two mirrors, each cemented at a single point to the glass fibre itself, one just below the upper clamp, the other just above the lower clamp. The upper mirror merely served, by means of a subsidiary lamp and scale, to bring back the part of the fibre to which it was attached to its initial position. The motion of the lower clamp was damped by attaching to it a vane dipping into a vessel of oil. The temperature of the room when the experiments were tried ranged from 13° C. to 13·8° C., and for the present purpose may be regarded as constant. The lower or reading scale had forty divisions to the inch, and was distant from the glass fibre and mirror 38⅜ inches. Sufficient time elapsed between the experiments to allow all sign of change due to after-effect of torsion to disappear. In all cases the first line of the table gives the time in minutes from release from torsion, the second the deflection of the image from its initial position in scale divisions.

Experiment VI.—Twisted for 121 minutes.

t	½	1	2	3	4	5	7
Scale divisions	191	170	148	136	126½	119½	108½
t	10	15	30	65	90	120	589
Scale divisions	97	84½	63½	41½	34	28	3½

The time was taken by ear from a clock beating seconds very distinctly.

The first point to be ascertained from these results is whether or not the principle of superposition, assumed by Boltzmann, holds for torsions of the magnitude here used.

If the fibre be twisted for time T through angle X, then the torsion at time t after release will be $X\left\{\psi(T+t) - \psi(t)\right\}$ where

$$\psi(t) = \int \phi(t)\, dt.$$

If now $T = t_1 + t_2 + t_3 + \ldots$ we may express the effect of one long twist in terms of several shorter twists by simply noticing that

$$X\left\{\psi(t) - \psi(t+T)\right\} = X\left[\left\{\psi(t) - \psi(t+t_1)\right\} + \left\{\psi(t+t_1) - \psi(t+t_1+t_2)\right\} + \left\{\psi(t+t_1+t_2) - \psi(t+t_1+t_2+t_3)\right\} +, \&c.\right]$$

Apply this to the preceding results, calculating each experiment from results for shorter time. Let x_t be the value of $\psi(T+t) - \psi(t)$, that is, the torsion at time t, when free, divided by the impressed twist measured in same unit; we obtain the following tables of comparison:—

Results for T = 121 compared with those from T = 20.

t	½	1	2	3	4	5	7
x_t observed ...	c·00979	871	758	697	648	612	556
x_t calculated ...	—	1070	950	880	830	780	730
t	10	15	30	65	90	120	589
x_t observed ...	497	433	325	212	174	144	18
x_t calculated ...	670	600	500	380	350		

The three last tables agree in indicating a large deviation from the principle of superposition, the actual effect being *less* than the sum of the separate effects of the periods of stress into which the actual period may be broken up. Kohlrausch finds the same to be the case for india-rubber, either greater torsions or longer durations give less after-effects than would be expected from smaller torsions and shorter periods.

The deviation from formula $\phi(t) = \frac{A}{t}$ appears to indicate the form $\phi(t) = \frac{A}{t^{\alpha}}$, α being less than, but near to, unity. If $\alpha = 0{\cdot}95$ we have a fairly satisfactory formula.

$$x_t = A'\left(\overline{T+t}^{\frac{1}{20}} - t^{\frac{1}{20}}\right), \text{ where } A' = \frac{A}{t_2} \text{ when } T = 121.$$

In the following table the observed and calculated values of x_t when T = 121 are compared, A′ being taken as 0·032.

t	½	1	2	3	4	5	7
x_t observed ...	0·00979	871	758	697	648	612	556
x_t calculated ...	0·00976	870	755	691	643	600	550
t	10	15	30	65	90	120	589
x_t observed ...	497	433	325	212	174	144	18
x_t calculated ...	493	429	320	218	176	147	42

Taking the formula $\phi(t) = \frac{A}{t}$ these experiments give values of A ranging from 0·0017 to 0·0022. Boltzmann for a fibre, probably of a quite different composition, gives numbers from which it follows that A = 0·0036.

In my paper on "Residual Change of the Leyden Jar," that subject is discussed in the same manner as Boltzmann discusses the after-effect of torsion on a fibre, and it is worth remarking that the results of my experiments can be roughly expressed by a formula in which $\phi(t) = \frac{A}{t^{\alpha}}$. For glass No. 5 (soft crown) $\alpha = 0{\cdot}65$, whilst for No. 7 (light flint) it is greater; but in the electrical experiment no sign of a definite deviation from the law of superposition was detected.

Geological Society, November 20.—R. Etheridge, F.R.S., vice-president, in the chair.—Rev. James Crompton and John Dennis Paul were elected Fellows.—The following communications were read:—On the upper greensand coral fauna of Haldon, Devonshire, by Prof. P. Martin Duncan, F.R.S. The author in this paper stated that since the publication of his supplement to the British fossil corals, published by the Palæontographical Society, several new corals have been obtained at Haldon by Mr. Vicary, of Exeter. Twelve additional species were noticed, of which ten were new. This brings the total number of species in the Haldon Greensand up to twenty-one. The new species are thus distributed:—*Aporosa:* Oculinidæ (1), Astræidæ (3), Fungidæ (5); *Perforata:* Turbinariæ (2); *Tabulata* (1). The paper concluded with remarks on the genera and species represented, from which it appeared that the coral fauna of Haldon is the northern expression of that of the French and Central European deposits, which are the equivalents of the British upper greensand. The Haldon deposit was formed in shallow water, and the corals grew upon the rolled *débris* of the age.—Notes on *Pleurodon affinis*, sp. ined., Agassiz, and description of three spines of cestracionts from the lower coal-measures, by J. W. Davis, F.G.S.—On the distribution of boulders by other agencies than that of icebergs, by C. E. Austin, C.E., F.G.S.

December 4.—Henry Clifton Sorby, F.R.S., president, in the chair.—Rev. William H. Allen, George Grey Butler, John Dixon, Rev. William Downes, B.A., Joseph Drew, M.D., Arthur Tom Metcalfe, E. P. Monckton, M.A., Albert J. Mott, Philip Lutley Sclater, Ph.D., F.R.S., William Hobbs Shrubsole, and Alexander Thuey, were elected

Fellows of the Society.—The following communications were read:—On some mica-traps from the Kendal and Sedbergh districts, by Prof. T. G. Bonney, F.R.S., and F. T. S. Houghton, B.A. The rocks described by the authors are mapped by the Geological Survey on quarter sheets 98 N.E., 98 S.E., and 97 N.W., and in parts briefly mentioned in the accompanying memoirs, under the generic name mica-trap. Seventeen examples are described macroscopically and microscopically, and of eight chemical analyses are given. It appears better to call one a porphyrite and two diorites (micaceous varieties). The remainder are all characterised by abundance of mica (biotite). Augite also appears to have been generally a constituent; but it has almost invariably been replaced by secondary products, calcite, dolomite, viridite, &c. Three are crystalline in structure; one of these is named minette, the others kersantite. The remaining eleven show a microcrystalline or cryptocrystalline base. It is proposed to call eight of them minette-felsite, the rest kersantite-porphyrite. These rocks commonly occur in rather narrow dykes; they are intrusive in Silurian strata, and, in the authors' opinion, are undoubtedly true igneous rocks.—Pleistocene notes on the Cornish coast near Padstow, by W. A. E. Ussher, F.G.S. In this paper the author described certain deposits seen in a small bay near St. Enodock's chapel, and known as Daymer Bay, and in section at Greenway cliffs.—The pleistocene history of Cornwall, by W. A. E. Ussher, F.G.S. In the first part of this paper the author, from his own observations and the writings of other geologists, gave detailed descriptions of the various superficial deposits of Cornwall, as exposed in numerous coast-sections. In the second part he discussed the relative ages of these deposits, and proposed a classification.

Physical Society, December 14.—Prof. W. G. Adams, president, in the chair.—Mr. W. Gleed and Mr. J. G. McGregor were elected members of the Society.—Prof. Guthrie read a note by Mr. C. Boys on a condenser of variable capacity. This condenser was designed for use in connection with the Holtz electrical machine to show the effect of condensation on the length of the spark. It consists of a test-tube coated externally with tinfoil to form the inner armature and a glass tube inclosing the test-tube, and having its outer surface covered with tinfoil for the outer armature. The inner tube can be slid out or in along the length of the external tube, and the capacity thereby varied. Prof. Guthrie showed that a spark from the Holtz machine could by its means be gradually reduced. Prof. Macdonnel stated that he had for some years used a similar apparatus, the inner coating, however, being strong sulphuric acid.—Dr. O. J. Lodge exhibited a differential thermometer in which saturated water vapour takes the place of air or other gas. This application is based on the fact that the pressure of a saturated vapour in contact with its liquid depends only on the temperature. An ordinary cryophorous answers the purpose when held so that the water occupies part of one bulb and a part of the stem next it; the greater the length of the water column in the latter, that is, the more horizontal the cryophorous is held, the greater the sensitiveness of the instrument. If, now, there be a difference of temperature between the two bulbs there will be a difference of pressure in the vapour in their interiors, and the level of the water will change until the pressure is equilibriated. When both bulbs are at one temperature the water in tube and bulb is on a level. Unlike air thermometers, the sensitiveness does not depend on the size of the bulbs or tube, and there is no increase of volume of the vapour. Another form consists of a U-tube, with bulbs at the end of each arm, each bulb having some liquid and the bend of the tube containing a short column of it, or, for greater sensitiveness, a series of films across the tube like diaphragms. This thermometer is found to be correct for temperatures below that of the ordinary temperature of the water and vapour, but inexact for high temperatures. With these latter the vapour tension is not the same throughout the tube, and distillation is set up. The instrument is a much more sensitive thermoscope than the air thermometer, and there is almost no limit to its sensitiveness to low temperatures. The radiation from the hand, held six inches from it, sensibly affects it, as also does the radiation from a piece of ice. For class purposes it is likely to be useful, from its simplicity and range of delicacy.—Mr. W. Clarke, Cooper's Hill College, from a series of experiments which he is making on the surface-tension of liquid gases, by means of their capillarity, gave the surface-tension of sulphurous anhydride as 2·3 milligrammes per square millimetre at −15° C.

Royal Microscopical Society, November 13.—Mr. H. J. Slack, president, in the chair.—A paper was read by Dr. Royston Pigott on some further inquiry into the limits of microscopic vision and the delusive application of Fraunhofer's optical law of vision, in the course of which he described numerous experiments to show that this well-known formula depends upon the laws of diffraction from rays reflected by bright discs or objects, but that it failed when applied to dark lines which were capable of being rendered visible far beyond the limits therein laid down. The subject was illustrated by numerous diagrams and by objects and apparatus exhibited in the room.—The President detailed the result of some recent experiments to determine the distance at which a human hair could be seen under various conditions by ordinary unassisted vision.—Mr. F. H. Wenham read a paper on the measurement of the angle of aperture of objectives, in which he described the method of measuring the true angle of aperture as distinguished from that of the angle of field with which it was commonly confused.—Mr. Henry Davis read a paper on the pygidium of insects, showing the organ commonly known by this name had its representatives in the Neuroptera, Gryllidæ, and other groups of insects, as well as in the flea and lacewing fly. He gave reasons for regarding it as a special organ of sensation conveying to the insect an intimation of the presence of dangerous enemies. Some discussion upon the subject took place between Mr. C. Stewart, Mr. Beck, Mr. Slack, and the author of the paper.—Some further communications, arising out of correspondence with Mr. Bedwell, were laid before the meeting by the Secretaries.—Three new Fellows were elected.

Institution of Civil Engineers, December 3.—Mr. Abernethy, vice-president, in the chair.—A paper was read on the heating and ventilating apparatus of the Glasgow University, by Mr. Wilson W. Phipson, M. Inst. C.E.

VIENNA

Imperial Academy of Sciences, October 17.—The following among other papers were read:—Remarks on Stephan's fundamental formulæ of electrodynamics, by Dr. Margules.—A hypothesis on the physical state of the sun, by Prof. Puschl.—Light as a reagent, by Herr Bohatta.—On the *Tonsilla* and *Bursa pharyngea*, by Dr. Ganghofner.

October 24.—On a simple apparatus for obtaining a constant gas pressure, by Dr. Handl.—A contribution to the doctrine of conic sections in descriptive geometry, by Prof. Miksic.—On meteorology of Alpine heights, by Dr. Hann.—On the formation of a space-curve of the fourth order, with a double point on a conic section.

November 7.—On the Venus transit of December 6, 1882, by Dr. Friesach.—Contribution to knowledge of internal friction in iron, by Herr Klemencic.—On the pitch of a tuning-fork in an incompressible liquid, by Prof. Kolacek.—Determination of orbit of the sixth comet of 1874.

ROBERT DICK OF THURSO

Robert Dick, Baker of Thurso, Geologist and Botanist. By Samuel Smiles, LL.D. (London: John Murray, 1878.)

BLEAK and bare, flat and featureless, the county of Caithness lies apart at the far end of Scotland, separated on one side from the rest of the country by rugged mountains and girdled on the other sides by boisterous seas—an unlovely region of brown moor and black morass, partially redeemed to agriculture along the sea-board, but so swept by storm and salt-spray that trees will not grow, save in a few sheltered spots where they have been carefully screened. The solitary mountain group of Morven and the Scarabins, visible from every quarter, lies at the far southern limit of the county, where it seems rather to be part of the uplands of Sutherland, to which indeed in structure it belongs. One redeeming feature, however, can be claimed for Caithness. It is one which compensates, or even more than compensates for the general monotony. The coast-line is almost everywhere formed by a range of mural precipices, rising here and there to heights of 200 and even 300 feet above the waves. Huge massive quadrangular sea-stacks tower out of the water in advance of the main cliff. The sea, moreover, runs inland in innumerable deep dark clefts or "gyoes," and is ever booming in the far recesses of caves that have been worn out of the solid rock by the chafing tides.

The monotony of scenery corresponds with, and indeed depends upon, the sameness of rock underneath. From one end of the county to the other the same interminable dark-grey flagstones in gently undulating beds underlie the scanty soil and peaty morasses. It is these rocks too which, truncated by the sea, run out boldly into headland after headland, or retire into sheltered bays and there extend in reefs upon the shore.

Over the wide Caithness plains the roads run in straight, unvaried lines for miles together. A curious consequence is alleged to be traceable in the physiognomy of the inhabitants. Two acquaintances, advancing along a road from opposite quarters, begin to recognise each other some time before they can actually meet. The smile of recognition is thus prolonged and fixed, so that the people are said to wear a characteristic Caithness grin.

A more unpromising field for the development of natural history tastes it might seem at first somewhat difficult to find within the compass of these islands. No lover of flowers is attracted to settle where short chilly summers and long damp stormy winters make up the year. And where flowers are few insect life will be scanty. Nor is the assemblage of birds likely to be varied where there is neither bush nor tree on which to perch or nest. The waters of these northern seas offer undoubtedly the greatest prospect of reward to the naturalist. They teem with life. Their plants and animals are cast up on the beach by every storm. Every pool on these rocky shores may be made a subject of patient and delightful study.

It was into the midst of these scenes that in the summer of the year 1830 fortune cast Robert Dick, then a young man of about twenty years. His life had not been altogether a happy one. The son of an officer in the Excise, he had received the ordinary education of a rural district in Scotland, and had shown such aptness at school that there was a proposal to send him to college with a view to his entering one of the learned professions. His father, however, married a second time. Robert's position at home eventually became so uncomfortable that at the age of thirteen he was glad to escape from the paternal roof and become apprentice to a baker in his native village of Tullibody, at the foot of the Ochil Hills. During his school days, and still when employed in distributing bread through the district, he developed an intense love for nature, which remained the master passion of his life. Flowers were his special study in these early years. He knew them in their abode in every bosky dell of his native hills, though as yet he had been able to learn little regarding their scientific names and classification.

With this yearning after wild plants and the scenes amid which they grow Dick came to Thurso (whither his father had already removed) and established himself there as a baker on his own account. His business, however, though he gave very diligent heed to it, did not afford occupation for more than a small part of his time. He was accordingly left with plenty of leisure for making himself acquainted with the natural history of his new home. The sea-shore naturally first attracted him. He wandered for miles along the coast, and collected such shells as he could procure from the beach. But he seems never to have thrown himself with zeal into the study of the marine fauna. His eye, indeed, was ever open, and, with the instinct of a true naturalist, he could recognise the value of facts in departments of knowledge with which he had little practical acquaintance. He ransacked the moors and mosses for beetles, bees, butterflies, and moths, gathering every species and variety he could find, and forming in this way a tolerably complete collection of the insect fauna of Caithness. Eventually he gave himself up, heart and soul, to the flora of the county, traversed on foot every parish and moor from end to end, and formed a herbarium containing not only each species of plant, with its locality and habitat carefully affixed, but also many singular and interesting varieties. He watched the vegetation from season to season, was familiar with the haunts of every species, knew when and where each began to show the earliest buddings, traced out the geography of the flora, and marked on what kinds of soil or rock particular varieties were to be found.

It was not until some years after his settlement in Thurso that he began to look into the rocks of the sea-shore. He stumbled upon scales of fishes imbedded within them, which greatly excited his wonder. Further examination brought to light abundant bones and plates, such as he could not find described in any accessible book. He began to collect these fossils, noting particularly the circumstances under which they occurred in the rock, and endeavouring to work out, as well as he could, their peculiarities of structure.

The way in which Dick found time for long excursions, without in anywise neglecting his business, brings out

the wonderful energy and enthusiasm of the man. He would bake his daily supply of bread in the early hours of the morning, have it ready for sale by his faithful housekeeper, and start off himself long before even the earliest riser in Thurso was out of bed. Often would he leave home about midnight, taking advantage of moonlight, and cross the county to reach some special ground for observation by daybreak. Yet he would always get home again in time for the preparation of next day's baking. In this way he would walk sometimes sixty miles or more in a single journey.

Of course such a man could not escape criticism in a small town where everybody knew everybody. And Dick's personal appearance not less than his singular occupations made him a "character" in Thurso. At dusk a tall figure with chimney-pot hat, swallow-tailed coat, jean trousers and travel-stained boots, usually with some bundle of stones, ferns, grass, or what-not, might be seen marching with a swinging pace towards the bakehouse in Wilson's Lane, and the neighbours would watch him as he passed, shrugging their shoulders, and wondering where the poor eccentric baker had been wandering this time. There was no congenial society for him in the place. Though naturally of a sunny hopeful temperament the bitterness of his early life had in some measure soured him; or at least had made him shrink within himself, avoiding the society of others, and finding his companionship among the flowers, mosses and rocks out of doors, and with his books at home. He was a diligent reader, not merely of such books on his favourite pursuits as he could afford to purchase, but of general literature, and in particular of poetry. He had considerable aptitude in quotation and availed himself freely of the gift in his letters. He taught himself drawing, also; turning the acquisition to account not only in the delineation of the objects of natural history which he encountered, but in such excursive subjects as Egyptian antiquities and classical figures, with charcoal outlines of which he would at times adorn the walls of his bakehouse. His artistic taste led him too to procure always the best edition of a book and to put it into the best style of binding.

Dick made Hugh Miller's acquaintance when that eminent writer was at the height of his reputation. There was much in the history and characters of the two men to draw them together. The one had told the whole world his story and had enlisted the sympathy of every reader in the pursuits that had made him famous. Dick on the other hand shrank from notoriety. He told his friend all he knew, showed him all his collections made him welcome to the use of everything, and took him over the ground whence he had quarried many a rare fossil. Such generous help could not but meet with fitting public acknowledgment from its recipient. "He has robbed himself to do me service," said Miller, who fully and frankly stated the nature and extent of his obligations; and then for the first time the geological world heard of the labours of the baker of Thurso. Dick, sitting by his own oven-mouth and reading the allusions to himself in Miller's paper, blushed to find himself thus in print, and begged that he might not be so often mentioned by name: "Leave it to be understood," he writes to Hugh Miller, "who found the old bones; and let them guess who can."

Nevertheless, like many self-taught men, Dick with this avoidance of publicity, united not a little vanity. He was proud of his humble position, and contrasted it with that of the "gentlemen-geologists," who could never do any good work for fear of soiling their clothes. He was proud of his prowess as a pedestrian, losing no opportunity of telling his friends how many miles he had walked and how many hours and minutes he had been on the tramp, while the "gentlemen-geologists" would have been in bed or lazily driving over the ground in gigs. He was proud of his achievements in science, of his power of seizing and sifting facts, of the collections which he had made, of the opinions he had formed. He had indeed much to justify this egotism, though few except the very limited number admitted into his intimacy, knew how much. Hence to ordinary acquaintances, or casual visitors he seemed morose, sarcastic, almost contemptuous. But above these little idiosyncrasies stood out bright and clear, his purity of character, his generous unselfishness, his enthusiasm for nature and his stern conscientious devotion to the daily drudgery of his business. His life was on the one hand a struggle with poverty, and on the other an exuberant communion with the works of God. After fifty-six years of such a life he died, leaving as the result of all his toil just enough of money to defray his debts.

It was well that such a story should be generally known. Dr. Smiles deserves our best thanks for having rescued it from oblivion and thrown it into the form of a volume, made up largely of Dick's own letters. It was fortunate that so many letters could be recovered, for otherwise, as Dick never published anything, and his friends were few, it would have been hardly possible to gather details enough for his biography.

The author has doubtless tried to do his best with the materials at his command, and nobody but he can know the difficulty of his task. But, in spite of the interest of his subject, he cannot be congratulated on having fully sustained in this new venture his well-earned reputation as a biographer. He appears to have taken up the life at intervals sufficiently removed to allow him to forget what he had already written, so that he repeats the same idea, sometimes almost in the same words. We are told three times, for instance, that there is no land between Thurso and Labrador, and twice within the space of three pages that Dick was a favourite with the children of his employer. Dick's habit of Sunday walking is referred to in Chapter XII., and after the lapse of more than a hundred pages it comes up again as if it had never been spoken of before. His baking operations, and how he carried them all on himself, are not likely to be forgotten by any reader of the volume.

More serious fault must be found with the inaccuracies of the book. The author states (p. 98) that "distinguished geologists had asserted that no fossil remains were to be found in the Scotch Highlands," and in support of this assertion he quotes a passage from Conybeare and Phillips's "Geology of England and Wales." The statement is meant to mark the importance of Dick's supposed discovery of fossil fishes in the Old Red Sandstone of Caithness. But a more unfortunate confusion could hardly have been made. In the first place, Caithness is not part of the Scotch Highlands. Geologically and

ethnographically it is a portion of the northern lowlands peopled by Scandinavian colonists. Again, while it is true that the rocks of the Scotch Highlands are with rare exceptions unfossiliferous, no geologist for half a century or more has said that those of Caithness are so also. Dr. Smiles, in repeating, amplifies his assertion (p. 245) and blunders still more; for this time he makes Dean Conybeare the author of the astounding statement that "the rocks of *Scotland* are unfossiliferous!" and drags in Sir Roderick Murchison, "who took the statement on trust," and "many writers" as propagating the delusion. A third time he refers to the subject, when (p. 238) he says "Robert Dick discovered numerous remains of fossil fishes in Caithness where distinguished geologists had stated that no fossil fishes were to be found." How he could print these sentences in the same volume with the letter from Murchison given on p. 275, it is hard to understand. In that letter Murchison speaks of himself as an old geologist who had written upon the Caithness fishes thirty-two years before. In truth, that geologist and his companion Sedgwick had found abundant fossil fishes in Caithness and had published an account with drawings of some of them, while Dick was still an apprentice carrying bread among the villages of the Ochils. No fact in Scottish geology was more familiar than that the flagstones of Caithness abounded in fossil fishes. That Dick should have been filled with surprise when he found them, only shows that he had not had opportunities of learning what had already been done in the district.

Again, Dr. Smiles refers to a remark of Sir Charles Lyell's that "very few organic remains had been found in the boulder-clay and especially in the till, throughout Scotland." It would seem as if he were quoting from a letter of Dick to Hugh Miller; for a passage from this letter follows, showing that the writer had found fossils in the boulder-clay almost in every place where he had looked for them. And the reader is left to draw the inference that Dick in testing Lyell's statement by an appeal to nature, had found it to be incorrect. But it remains absolutely true to this hour. The boulder-clay, as a whole, is singularly barren of organic remains. In one or two exceptional places, and Caithness is one of them, it is full of fragmentary marine shells. Dick's observations were quite accurate; but it was not necessary to enhance their importance by showing that they contradicted the published statements of so distinguished a writer as Sir Charles Lyell.

But the most serious defect of all is one with which it is somewhat difficult to deal. Every reader of the book will recognise that its preparation has been a labour of love. Dr. Smiles has wandered over all the scenes of Dick's rambles, has tried to realise as vividly as possible the circumstances and surroundings of the enthusiast's life, has recognised his devotion to the acquisition of knowledge, and has written with the most heartfelt sympathy with Dick's love of nature and the struggles and trials of his position. And yet one feels that into the spirit of the researches which formed the bright side of Dick's lonely life, which cheered him and furnished him with mental food and recreation from beginning to end, the writer of the Life hardly enters at all. It was more than a mere love of nature which carried Dick so buoyantly through his monotonous drudgery; more than the mere pleasure of finding flower, or insect, or fossil in its native habitat, and bringing it home to enrich his collection. We have glimpses of this in his graphic letters, and a reader who knows something of the contemporary history of scientific progress, can read between the lines of these letters and find in them an interest tenfold greater than they can possibly have without this information. The want of such assistance to an ordinary reader must make the letters somewhat monotonous, and give the impression that the book is unnecessarily long. When he reads, for example, Dick's account of his numerous and laborious traverses of Caithness in search of sections of boulder-clay, he will naturally ask the object of these toilsome journeys, what was to be gained from them, and what in actual fact was gained. It would have increased his appreciation of these labours to have learnt something of the problem to the solution of which Dick set himself, and he would have been the better able to realise the eager enthusiasm which led that votary of nature to cross the county on foot at night to get to his boulder-clay scars by daybreak. It would have heightened the reader's respect for the subject of the biography to have been shown how, if the results briefly sketched in the letters now published, had been given in detail to the world a quarter of a century ago, they might have placed the name of Robert Dick among the pioneers of glacial geology.

But of all this we learn nothing from the memoir. Dr. Smiles sums up Dick's character and points the moral to be drawn from the story of his life. But what was the outcome of these long years of indefatigable labour? Apart from the man himself, what did his work advantage the world? It is, indeed, a worthy thing to have lived a life that may serve as an ensample and encouragement to after generations. Dick did that nobly. But he did more. He felt that he had "done the State some service." Though he never published his knowledge he worked incessantly and freely communicated his stores of information to others. Much of that knowledge died with him. Yet from his letters, his scientific collections, the published references to the assistance freely given by him to fellow-workers in science, and the recollections of his contemporaries, it might have been possible to have given at least an outline of what he had achieved. Such a sketch would have been a fitting tribute to his memory, a recognition of the meaning and value of those long years of solitary toil.

In an interesting and genially written episode, Dr. Smiles sketches the career of another, but still living enthusiast in natural history—Charles W. Peach, who was one of Dick's most intimate friends, worked with him among the Old Red Sandstone fossils, corresponded, argued, battled with him over their respective opinions. But here again the writer's general sympathy with a heroic struggle for the acquisition of knowledge betrays no special interest in or acquaintance with the life-work of his hero. Unwittingly, therefore, he is led to do but scant justice to his subject. From the allusions, for example, in Dick's letters and elsewhere, to a discussion between that dogmatic observer and Mr. Peach regarding fossil wood, no reader could guess what a momentous point in the history of the Old Red Sandstone of Caith-

ness was really in dispute, and how much Peach's observations went to settle it. No one reading the volume, with its account of Dick's hammerings and Hugh Miller's visits and writings, could surmise that in the palæontology of the Old Red Sandstone of Caithness Peach has done far more than Dick, far more than Hugh Miller, more, indeed, than all other geologists put together.

The illustrations of Caithness scenery, plentifully interspersed throughout the book, are well engraved, and, on the whole, very faithful and characteristic. Nothing could be better than the Deil's Brig of Scrabster Bay. We see the very lichens quivering in the gusts that blow for ever through that hideous cleft, and we hear the screams of the northern sea-fowl as they wheel in restless circles from the neighbouring Clett. In transferring the author's sketches to the wood, however, the artists have taken a few liberties which would have roused poor Dick's indignation. Dirlet Castle, which stands on a rock some twenty or thirty feet above the stream, is raised at least 300 feet into the air; and dear old Morven, glorified into a second Matterhorn, is placed just opposite to Dick's contemptuous ridicule of what the books say about the hill—"None of the hills are as big as books make them"—"downright nonsense! Morven is accessible on every side."

ARCH. GEIKIE

TELEGRAPHY

Instructions for Testing Telegraph Lines and the Technical Arrangements of Offices. By Louis Schwendler. (London: Trübner and Co., 1878.)

THE criterion of the good working of a line of telegraph is its freedom from interruption. Interruptions to the communication are technically called "faults," and on our overground lines men are stationed at certain intervals for the express purpose of patrolling these lines and removing defects from them that sooner or later might culminate in faults. Of course accidents, such as those arising from snowstorms and violent winds, cannot be prevented, but most of the interruptions that are met with in practice can by proper supervision be eliminated before they can arrive at such a condition as to interfere with the communication. In telegraphy more than in anything else, "prevention is better than cure," and for many years past all our telegraph engineers who have devoted their attention to the proper maintenance of telegraphs have striven to devise as perfect a method as they can for detecting the presence of faults and for establishing an accurate system of testing.

It is, however, upon our submarine cables, not only in their manufacture but during the process of laying, and whilst subsequently working, that the greatest skill and ingenuity has been employed to devise a perfect system of testing.

The first rational mode of testing our cables was introduced by Dr. Siemens, but Mr. Varley had previously introduced into the service of a Telegraph Company a very elaborate system of testing by the aid of differential galvanometers and resistance coils. Rheostats or resistance coils had been invented by Wheatstone as far back as 1843, and Sir Charles Bright and his brother, Mr. Edward Bright, had introduced them into use on the Magnetic Telegraph Company's system. It was, however, in the telegraph companies' service that the system was to a certain extent perfected, and when all the systems of the different companies were concentrated into the hands of the General Post Office the system became universal for the whole country. We cannot think that Mr. Schwendler, when he asserts that no really practical system of testing had been adopted by any other telegraphic administration than that of India, could have been aware of the perfect system in use by our English administration, and it is a pity that he has not embodied in his book a description of the system in use in England. This perhaps is unnecessary, because it is fully detailed in the "Handbook of Practical Telegraphy," by Mr. Culley, and in the textbook of science on "Telegraphy," by Messrs. Preece and Sivewright. Moreover, there is an excellent little "Handbook of Testing" detailing not only the practice on land lines but on cables also, by Mr. H. R. Kempe, and with another capital little book by Capt. Hoskiaer, on "testing cables," as well as a work on "Electrical Measurements," by Mr. Latimer Clark, leaves very little to be desired on the literature of the subject. Mr. Schwendler really adds little or nothing to our knowledge of the subject, and his book is only valuable as an indication of what has been done in India.

Great strides have been made in the Telegraphic Department in India ever since the accession to power of the lamented Col. Robinson. There is, according to Mr. Schwendler, a large staff of officers available with a first-rate general education and with a strong desire for improvement, and many of them are well trained in conducting physical experiments. It is to be hoped that their education is sufficiently advanced to enable them to follow the rather intricate mathematical developments of Mr. Schwendler. If his book has a defect it is that it is overloaded with mathematical investigations. There is no necessity to appeal to laboured formulæ when simple observations alone are needed to interpret phenomena. The mathematician loves his formulæ as a hen her brood, but the practical man prefers to kick them aside when he can do so and when he can do without them. Now, at p. 16, Mr. Schwendler gives no less than six elaborate formulæ, one of which must be selected for each particular condition to enable the tester to discover the value of any foreign electromotive force that may be in the circuit, the result of what he calls a "natural" current. Now there is no necessity whatever for any formula. The elimination of earth currents in cable and land testing is of daily and constant occurrence, and it is only necessary to compare the deflection upon any galvanometer given by the earth current with a deflection produced by one cell through similar resistance to find its value. Readings by reversals when taken rapidly always give a mean that is approximately true, for an earth current rarely varies so rapidly as to introduce any sensible error. His formulæ for eliminating the electromotive force when measuring with a differential galvanometer simply appal one.

Mr. Schwendler wisely says, "however much testing may become routine by continual practice it *will* always and *should* always partake of something of the nature of a physical experiment which must be conducted with a perfectly clear understanding. Then only can the tester draw the right conclusions from his observed facts; then

only can testing become a real benefit to the administration."

Again he says, "We know quantitatively the electrical state of the lines at all hours of the day, and seasons of the year; we are able to localise faults of all kinds very accurately and repair them with despatch; we test all our telegraphic material, and by it have greatly improved its essential qualities; we are not groping in the dark any more—we *measure* and *know*."

It never must be forgotten that testing is in reality a physical experiment, and these physical experiments are being conducted every day throughout the whole of our English telegraph system. Our cable electricians under the guidance of Sir William Thomson have carried this system of physical experiment to a high standard of perfection, and our Indian friends would do well to profit by their teaching.

Mr. Schwendler's explanation of the theory of the bridge is not clear, nor does his use of Kirchhoff's corollaries to Ohm's law much help the student. Indeed it is very doubtful whether his proof that the sensibility of the bridge method is greatest when the branch and the resistance are equal is true. At any rate in our practice we find that the more delicate the galvanometer of the bridge the more sensitive and the more accurate is our test.

The most valuable portion of Mr. Schwendler's book is his abstract of Ohm's classical paper, a translation of which is to be found in Taylor's "Scientific Memoirs," and also in his account of Kirchhoff's corollaries to this law.

The practice generally of line testing and testing for faults contains nothing new, but his chapter on natural currents, showing the effect of polarisation of earth plates and the presence of earth currents, is interesting.

He says, also "*Defective insulation at a few points* in a line is a fruitful source of currents. At all such points polarisation is produced by the working currents, in a manner precisely similar to that of the earth plates, by the same cause already alluded to, and to a degree dependent on the resistance and the position of the faults. These currents will be strongest in rainy weather, when the line is in contact with trees, when the insulators are covered with dew—in fine, under those circumstances which diminish the resistance of faults and promote electrolytic action.

"The stronger the working currents used, and the fewer the defective points, the stronger will be the polarisation currents.

"If these currents become very strong their direction may be reversed by sending for a short time a strong current with zinc to line; and, in such a case, this invariably indicates a single fault in the line or cable." This is a defect which we do not experience in England.

We find that (p. 66) "on all the lines in India positive signalling currents (copper to line) are used in order to have the greatest possible insulation of each line under all circumstances. Now, when measuring the insulation of a line with a positive test current, it is evident that the value obtained must give the insulation much too high, *i.e.*, higher than the line actually has when signals pass through it; because the signalling currents can only have a comparatively small oxidising effect on the line, since only a very small part can escape to earth in the different points of the line, while a positive testing current, the further end of the line being insulated, must all escape to earth at the defective points of the line. Again, when measuring the insulation of a line with a negative testing current, we get a value which gives the insulation of the line much too low, because negative signalling currents are never used. In the absence of any known law, which would give us how much too high the insulation of the line is obtained with a positive testing current, and how much too low with a negative testing current, we can do nothing better than to take the arithmetic mean of the measured values as representing the insulation the line probably has when signals are passing through it. Of this mean it may, however, be said that it must be always somewhat too low, for the very reason that negative signalling currents are never used, and therefore the arithmetic mean again of the *first mean* and the *positive measured value* would represent a value most probably approximating to the one which the line actually has when signals pass, and which alone is of practical interest and consequence to be known."

The latter part of the book is devoted to fault testing, *i.e.*, to the localisation of the positions of faults.

The book itself is a very valuable addition to the literature of the subject, but we doubt whether it will be of any practical use to our English electricians.

OUR BOOK SHELF

Sketches of Wild Sport and Natural History of the Highlands. By Charles St. John. Illustrated Edition. (London: Murray, 1878.)

MANY of our readers must be familiar with the inimitable "Sketches" of St. John, which has long ago achieved the position of a classic for both the sportsman and the naturalist. We do not know of any descriptions of sport to equal those that abound in these pages, in truthfulness, vigour, and genial humour. To the naturalist who loves to know the habits of an animal in its native haunts, the book must be a treasure; and now that Harrison Weir, Whymper, Corbould, Collins, and Elwes have adorned it with their art, the book should become a greater favourite than ever. No artist equals Whymper in his faithfulness to life in drawing animals. Every picture in the book—and there are about eighty of them—is a masterpiece in its way, and an impressive lesson in natural history. We need only say that the engraver is Mr. J. W. Whymper to convince our readers that the artists' charming work has been faithfully and skilfully rendered. No one can read a chapter of the book without being both refreshed and instructed.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Paradoxical Philosophy

IT is strange to see a writer on philosophy like Mr. S. H. Hodgson, as well as physicists so exceptionally able as Prof. Clifford, and now Prof. Clerk-Maxwell, falling into the same *errors of observation* as more ordinary mortals. Neither the authors of the "Unseen Universe," nor any of the members of the Parodoxical Society, have, so far as I am aware, expressed the

notion that the invisible order of things which continuity requires as antecedent to the visible order, is in any sense *material.* They only assume that it must be conditioned. Indeed, the authors of the "Unseen Universe" have expressed this conviction *in the preface to the second edition of their work, in italics, and in language that is not only exceedingly clear, but also extremely strong.*

But it seems to be taken for granted on all sides that a man of science can only imagine a mechanical unseen. This is really very hard.

The analogy (however inadequate) furnished by Thomson's vortex atoms, and the invisible fluid which they postulate, is too good an *illustration* of a novel and difficult conception to be disregarded; but it will have to be laid aside at once, if it can be shown to be necessarily productive of such extraordinary misconceptions even in intellects of the highest order.

HERMANN STOFFKRAFT

Schloss Ehrenberg, Baden, December 25, 1878

Force and Energy

SINCE a year or two back, when Herbert Spencer started, in the columns of NATURE, a discussion as to the real meaning of the word "force," most careful-thinking students of mechanics have probably come to the conclusion that either the use of the word "force" must be discontinued as a physical scientific term, or that it must be defined in a different manner from that adopted almost universally by those "doctors" whose writings seemed to weigh so heavily on the brain of "poor Publius." They all agree in saying that in its physical application the word "force" means that which produces *i.e.*, the CAUSE of change of momentum. It is needless to give quotations. They are all, except one, curiously explicit. Germans, French, and English agree. "So sehen wir diese Aenderung als Wirkung irgend einer in demselben thätigen Ursache an; diese URSACHE nennen wir Kraft." (Ritter's "Mechanik," p. 36). "On donne, en general, le nom de FORCE à la CAUSE quelconque qui met un corps en mouvement, ou seulement qui tend à le mouvoir." (Poisson: "Traité de Méchanique," Introduction, p. 2.) Although in Tait's "Recent Advances" we find on p. 11 "that we have not yet quite cast off that tendency to so-called metaphysics which has so often blasted," &c., &c.; yet on p. 16 of the same book there is reproduced the fine old crusty Newtonian maxim to which Thomson and Tait and Tait and Steele cling with such fond reverence: "force is any CAUSE which," &c. Clerk Maxwell gives no formal definition of force in his "Electricity and Magnetism." On p. 5 he simply gives its dimensions. On p. 83 of his invaluable "Theory of Heat" he defines, "force is WHATEVER changes or tends to change," &c. This is a very ingenious mode of escaping the difficulty by simply giving no definition at all. We are told what the result of force is, but not what force itself is. We are told that force is "whatever," which is not very clear. Jeames would hardly think that justice was done him if we asserted that the complete definition of him was "whatever opens a door," and made no mention of the fact of his humanity or of his grand plush breeches. It is, in fact, a confusion between a statement of the mode of measuring quantitatively the force, and the definition of the force itself. A physical definition should certainly show clearly what the proper way of measuring the quantity is; but this latter is not the definition itself. Moreover, there may be different almost equally good modes of measurement, all leading to the same numerical result. Clerk Maxwell's definition is clear as to *a* mode of measuring force, but furnishes absolutely no information as to the nature of the thing intended to be defined. It, therefore, differs from the others in that they are real metaphysical definitions, presumably comprehensible to those who understand metaphysics, while his is no definition at all. Prof. John Perry, in his book on "Steam," adopts the same device as Prof. Clerk Maxwell, substituting the word "anything" for "whatever." Rankine forms a remarkable exception. He says that "force is an action between two bodies either causing or tending to cause change in their relative rest or motion." Here the word "cause" is used in such a sound, practical, common-sense way that no one could take exception to such use of it, even in a physical definition, and probably "action," as here used, might be explained clearly enough for all useful purposes as "a changing relation" or "a change of relation." Rankine, however, does not take the trouble to do this last.

Now clearly a cause is a metaphysical entity, if it is an entity at all, and from the very nature of the difference between metaphysics and physics, a metaphysical entity cannot possibly be made of any use in physical investigations. If, then, the word force is to be usefully employed in physics, it must be defined as something else than a "cause." When we talk of forces, the physical facts the observation of which we think of, are accelerations of momentum; and in his Glasgow lecture Prof. Tait seems half inclined to use "force" and "acceleration of momentum" as synonymous terms. But an acceleration of momentum is a function of one body only; and every one knows that what is mentioned in Rankine's definition is true, namely, that force is a function of two bodies, and can have neither objective nor any other kind of existence except as a relation between two bodies. Seeing that it is so, I beg to lay before your readers for their favourable consideration the meaning of the word force which I have used for several years past. I wish force to be defined as "time rate of transference of momentum." A transference of anything can only take place between one body and another, and in the transference the amount transferred from the first body to the second is necessarily equal to the amount transferred to the second body from the first. This might seem to be such a truism as to be a mere repetition of words; but we must remember that it is the law of motion which the "transcendently lucent" Newton discovered from his extensive physical experience; and, in order to discountenance scepticism, we might add, by way of parenthesis, that during the transference no spilling takes place.

"Poor Publius" might thus get a hint that there is such a physical fact as conservation of momentum which is independent of all formal definitions. If momentum is conserved, *i.e.*, if it has an enduring existence so that at one time there is no more nor less of it than at another, then during a direct transference of some of it from one part of the system in which it is lodged to another part, the amount lost by the one part must evidently be the same as that gained by the other part. Thus an acceleration or time-rate of gain of momentum to one part necessarily implies a simultaneous equal time-rate of loss of momentum from another part, and also a simultaneous equal rate of transference of momentum from that other to the first part. All these three rates have directions inasmuch as they are time-rates of directed quantities. The first is a rate of gain of momentum, which momentum has a certain direction. If that direction be reckoned positive the gain is one of positive momentum, and the acceleration is naturally reckoned as positive. The second is a rate of loss of momentum of the same direction, *i.e.*, a loss of positive momentum which is equivalent to a gain of negative momentum, and therefore this time-rate is naturally reckoned negative. The meaning of this is simply that the proper physical sign to ascribe to acceleration of momentum is the directional sign of the momentum gained. The two opposite signs of the above two rates have given rise to the idea of two equal and opposite forces acting between the bodies. If the forces were located IN the bodies and not BETWEEN them, the phraseology would be consistent with Tait's definition of force as simply "acceleration of momentum." But I do not hesitate to say that this idea of force is quite unnecessarily out of accord with the commonly received notion of force as a mutual action or relation between TWO bodies, because in this view force would distinctly have reference to only one body. If, however, we use force to mean the transference of momentum, there is, of course, only one force between the two bodies. The question is what sign is to be given to this force, and it is not quite easy to answer. Force is in this view a flux, a rate of flow of momentum. This flow takes place in a certain direction, and it is the flow of a directed quantity. Are we to take the direction of the flow or the direction of the momentum that flows, to determine the proper sign of the force? These two directions need not be the same. Thus in a bar subjected to tension the flow of momentum is in the direction opposite to that of the momentum itself. In a bar in compression the flow of momentum takes place in the same direction as that of the momentum. In a mass subjected to shearing stress the direction of the flow is perpendicular to that of the momentum. In the case of the attraction of gravitation between two bodies the direction of the flow of momentum is always the exact opposite of that of the momentum that flows from one to the other in whatever way the two may be moving. In the case of impact if we take the direction of the flow of momentum as that of the perpendicular to the surfaces that touch during impact drawn from the body that loses momentum towards the body that gains momentum, then this direction of

flow may make any angle within certain limits with that of the momentum exchanged. If we are to adhere strictly to the ordinary conventions with regard to the directions of forces, it is clear that we would need to consider the transference of momentum which we term force, only with reference to the direction of the momentum transferred, and without any reference to the direction of transference. It is, however, evident that this latter direction is of very great importance in physical investigation, and it is a matter worthy of serious consideration whether or not force should not be considered a two-directional quantity, one into whose definition two directions enter. Impact is a difficult subject, perhaps, just because of the large possible variation of the difference of these two directions. All other forces (rates of transference of momentum), except those involved in impact may be divided into three simple classes corresponding to compression, tension, and shear.

In considering stress, the phrases "transmission of momentum" and "rate of transmission of momentum" are as convenient, perhaps, as the corresponding phrases with "transference" substituted for "transmission."

The most obvious objection to this definition of force is that a force may be applied to a body, and yet it receives no momentum. The objector would probably say that though the force be applied, yet there may be no momentum transferred to the body. But this would be quite wrong, as can be most easily recognised if Prévost's theory of exchanges of heat by radiation and the similar theory for conduction of heat be recalled to mind. A body may quite easily have simultaneously equal amounts of opposite momentum transferred to it. These will balance, and its centre of gravity will suffer no acceleration of velocity. This remark will make it evident that the theory of force gives an easy and unhesitating answer to the much-debated question as to whether there are really such things as unbalanced forces. A transference of momentum between two bodies may just as readily be unbalanced as balanced. Let us consider this balancing of transferences of momentum more particularly. Let a body have momentum transferred to it by the pressure of another body upon a certain portion of its surface. This can be balanced in different ways. It may be balanced by a perpendicular pull applied to a portion of the surface parallel to that to which the pressure is applied, and facing the same way, *i.e.*, on the same side of the body. The directions of the momenta transferred at these two surfaces are the same, but the directions of transference or flow are opposite. Or the pressure may be balanced by an oppositely directed pressure upon a parallel surface facing the other way. In this case the directions of the momenta transferred at the two surfaces are again the same, while the directions of flow are also the same. In all cases when a body is kept in balance by transferences of momentum going on through its different surfaces, it is evident that for any amount of momentum of a given direction transferred into it at one surface an equal amount of momentum of the same direction must be transferred out of it at some other surface. The directions of transference or flow at these two surfaces may be relatively any whatever—they are quite independent. The balance of the body, with respect to the velocity of its centre of inertia, is quite uninfluenced by the directions of the momentum-flows through its different surfaces. But evidently the state of stress and strain throughout the interior of the body depends a great deal upon the relative directions of these flows as well as upon the relative positions of the surfaces.

But, as regards the direction of the momentum, it must be remembered that this depends upon what we arbitrarily choose to be our standard positive direction, whereas the equilibrium of the body acted on certainly does not depend in the least upon that arbitrarily chosen direction. Thus, as in the above example, let the body 2 be kept in equilibrium by the equal and opposite pressures of the bodies 1 and 3 on its opposite faces. The question is whether momentum is being transferred from 1 to 2 and from 2 to 3, the momentum transferred having also this direction; or whether both the flow and the momentum flowing have exactly the opposite direction, viz., from 3 through 2 to 1. If we have a standard positive direction to go by, and if 1 is not in equilibrium, but is being stopped in its motion by impact on 2, then the above question is easily answered at once. But if 1 is in equilibrium as well as 2, we must, in order to answer the question, look beyond 1 to find out the direction of the other transference of momentum, which, along with that between 1 and 2, keeps 1 in equilibrium. If this other transference takes place between 1 and another body which is again in equilibrium, it would be necessary to go back still another step in order to find out in which direction the flow is really taking place. If the whole system of which these bodies form parts is everywhere in equilibrium, *i.e.*, all the parts at rest relatively to each other, we would in this way travel from one body to another in a complete circuit in search of some point which would disclose the real direction of flow, but without ever coming to any such point. Because, following round the circuit, we would again come back to 3 and 2 and 1. The choice of a standard direction as the positive one does not help us in the least to come to even a formal conclusion. We remain, however, sure of two things—first, that there is really a continual flow of momentum taking place all round this circuit in the system; and, secondly, that the direction of this flow is at some places, which we can definitely specify, in the same direction as the momentum transferred, and at some other places, equally easily specified, in the opposite direction. Take as an example a piano. We may suppose the upper horizontal bar of the frame to which the strings are attached to be continually losing upward momentum, which is being continually received by the top parts of the tightened strings. This upward momentum the strings are continually transmitting downwards from particle to particle, and at the foot of the strings it is delivered to the bottom horizontal bar of the frame. This bottom bar transmits the upward momentum horizontally, each section being in shear, to the vertical sides of the frame. The transmission down the wire is in the direction opposite to that of the momentum transmitted; in the horizontal bottom bar the direction of transmission is perpendicular to that of the momentum, through the sides this momentum flows upwards, that is, in the same direction as the momentum itself, and finally, it is transmitted again horizontally through the upper bar to be redelivered to the strings. This explanation is completely satisfactory in accounting for the conditions of strain of the various parts of the piano. But to explain these conditions an equally satisfactory hypothesis would be that a stream of downward momentum is continually circulating through the piano in the same circuit as the above, but in the opposite direction round that circuit. Or again we might suppose two opposite circulations to be continually going on, one of upward momentum and the other of downward momentum. But whichever of the three hypotheses we may adopt, we always have the flow in the string which is in tension opposite to the momentum flowing through it, and the flow through the horizontal bar perpendicular to the momentum, and the flow through the sides of the frames in the same direction as the momentum transmitted.

Which of the three is to be chosen, or is it of any consequence that we should know which should be taken? The question is not one that can be made to have any degree of unreality in appearance by merely measuring the motions relatively to one thing or another. It is not whether the momentum transferred is upward or downward relatively to the centre of the earth, or relatively to the sun or to the stars. It is, what is the direction of this momentum relatively to the centre of inertia of the piano frame itself, whether this relative momentum is directed from one end of the piano towards the other or from that latter to the former, and the answer to this question is quite independent of what we arbitrarily choose to call the absolute velocity of the centre of inertia of the whole structure.

I will venture to say that the correct answer is that there are two opposite streams of equal amounts through the structure. What is meant by equal amounts is, of course, that the opposite rates of transference through any section are numerically equal. The simplest and clearest proof is this very simple one: If there were only one stream circulating in one direction, since from the above it is clear that the momentum flowing along in this stream is at every point of it of the same direction, and since the stream is a continuous steady one, every part of the structure through which this stream flows would have the velocity corresponding to this momentum, and in consequence the centre of inertia of the structure would have a certain velocity in the same direction. The inconsistency of this result with the datum from which we started, namely, that the momentum transmitted was to be measured relatively to the centre of inertia, need not be pointed out. To look at the question in another way, let us only consider what this momentum, this thing that is being transferred from particle to particle, really is, viz., mass multiplied by velocity, and we cannot fail to come in a moment to the conclusion that these streams are simply streams of molecular vibration.

And since each particle maintains constantly the same average position relatively to the centre of inertia of the whole, it is evident that its alternate opposite displacements and velocities relatively to that centre of inertia must be numerically equal. A certain particle has first a certain velocity in one direction, and immediately afterwards has a numerically equal velocity in the opposite direction. This change cannot take place except by its transferring to the next particle the same numerical amount of momentum of one direction as it receives from that particle of momentum of the opposite direction. In this way constant streams run in the two opposite directions, the momentum flowing along one having the opposite direction to that flowing along the other, and equal numerical amounts of these oppositely directed momenta flowing past any given sections of the two streams per unit of time.

As a sort of parenthesis let me give the following symbolical statement of the foregoing. Let V be the velocity of flow of either of these two opposite streams, and μ the mass per unit volume of the material, and v the average numerical velocity of the particles. Then since at any given instant half the particles must be supposed to be moving in one direction, and the other half in the opposite direction, the amount of momentum of one direction passing per unit of time through any section of unit area of the correspondingly directed stream, is $\frac{1}{2} V\mu v$. A numerically equal amount of oppositely directed momentum is flowing per unit of time through the same unit section in the opposite direction. Observe that the material through which these two streams are flowing is in "balance," "in equilibrio." Suppose the one stream to lead out of, and the other to lead into, an unbalanced mass, which mass suppose not to be losing or gaining momentum except by these two streams. By means of the one it loses, say $(+\frac{1}{2} V\mu v)$ per unit of time. By means of the other it gains $(-\frac{1}{2} V\mu v)$ per unit of time. The amount of positive momentum it transfers to the balanced material for unit of time is, therefore, $+V\mu v$, and this is the rate of transference of momentum from the unbalanced mass to the balanced material, and through this latter. If the ratio of comparison or extension, *i.e.*, the strain of this balanced material, be called e, then what we usually call its modulus of elasticity is E given by the equation $eE = V\mu v$. If we insert in this expression the proper value of $V = \sqrt{\frac{E}{\mu}}$, the velocity of transmission of longitudinal vibration, we obtain a value of $v = e\sqrt{\frac{E}{\mu}}$, similar to that deduced by De St. Venant for the first stage of an impact, during which a single *unbalanced* wave of momentum is running forward through the body impinged on. But the important point to notice is that the rate of transference of momentum per unit area is the product of a mass per unit volume (μ) and of two velocities (V and v). In unbalanced transmission these two may be in the same direction, in which case the mass being accelerated is in compression, or they may be in opposite directions, in which case the accelerated mass is in tension; or they may be at right-angles, in which case the accelerated mass is in shear. In balanced transmission if in the one stream the velocity of flow is in the same direction as that of the flowing momentum, then also in the opposite balancing stream these two velocities have the same directions and the material is in compression, the strain being double that which would occur if either of these opposing streams existed by itself unbalanced in the material. Similarly for a balanced state of tension and for one of shear.

Considering these reasonings, does it not seem right to make the direction sign of the force, or rate of transference of momentum, the same as that of the product of these two velocities. The sign of the product of two vectors does not depend on the absolute direction of either, or rather it does not depend on the relation of either to what we arbitrarily choose as our standard direction. It depends only on their mutual relation. Thus we get a definite sign for each force not arbitrary, but real. For a compression force the two vectors have different signs, and their product is a multiple of -1. For tension, the two being of the same sign, their product is a multiple of $+1$. For shear, the two being perpendicular, their product is a multiple of $\sqrt{-1}$ or of $-\sqrt{-1}$. If the direction of transference be oblique to that of the momentum transferred, their product is the sum of a scalar and of a vector. In this case we have compound stress, that is a shear compounded with either compression or tension; and, as every one knows, it is usually convenient to consider the scalar and the vector parts separately. The question of the *mode* of transmission of momentum corresponding to these main kinds of stress is one of molecular mechanics, into which there is no need of entering here.

Leibnitz's Mathematics

IN perusing some old files of NATURE I came upon the following sentence in a letter from Prof. Tait (vol. v. p. 81) in reference to the invention of the Differential and Integral Calculus:—"Leibnitz was, I fear, simply a *thief* as regards mathematics." Prof. Tait has more than once intimated or expressed a similar opinion.

In reply to this imputation Dr. Ingleby says (NATURE, vol. v. p. 122):—"I do not object to the Professor calling a spade a spade; but I assure him that this charge is made just twenty years too late. It is exactly that time since the *last vestige* of presumption against the fair fame of the great German was obliterated. If Prof. Tait does not understand me, or, understanding me, disputes the *unqualified truth* of my statement, I promise to be more explicit in a future letter. But I incline to think the question is not susceptible of *proof* until the Council of the Royal Society, who so grossly disgraced themselves in 1712, shall do the simple act of justice and reparation required of them, viz., publish the letters and papers relating to this controversy, which since that date have slumbered in the secret archives."

Prof. Tait, as far as I know, never responded to the challenge, and I presume there is but one inference to be drawn from his silence.

In a late reading of an account of this controversy from the German standpoint, my interest in the subject has been reawakened, and I feel a strong desire to see the whole question thoroughly ventilated. Such a consummation must surely be wished by every fair-minded man, and in the name of justice I would ask Dr. Ingleby to be more explicit and do what lies in his power to remove the imputation which has been attempted to be fastened upon Leibnitz.

This question will not down at the bidding of any one, and the documentary evidence alluded to by Dr. Ingleby must sooner or later see the light. Let us have the matter at once and for ever definitely and honourably settled. A. B. NELSON

Danville, Ky., U.S.A., November 27, 1878

[It is not to be absolutely presumed that, when a busy scientific man lets pass such challenges, he has given up his point. The question has now lost all but a species of antiquarian interest:—still it is worth clearing up. We might begin by asking Mr. Nelson and other defenders of Leibnitz to explain the very singular appropriation which Leibnitz made of "Gregory's Series" *after* having acknowledged whence he got it.—ED.]

Commercial Crises and Sun-Spots

A SUGGESTION is made by Mr. John Kemp, in NATURE, vol. xix. p. 97, to test the relation of sun-spots to the variation in weight of the cereal grains. Probably the difficulties of giving such a test scientific precision are insurmountable. No doubt these grains do vary in weight from year to year. Of some samples of oats, of crop 1877, contributed by me to the South Kensington Museum, the pound contained 13,642 grains, while the pound of crop 1878 contained 16,870. But there are many varieties of oats, barley, and wheat in general cultivation, each producing grains differing in weight from the others. In an inquiry which I made regarding the weight of the *sterling*, average grains of wheat of crop 1876 from the south of England were found, in an air-dry condition, to weigh as follows: Talavera, 1·01 gr. troy; Chidham white, ·76; Sherriff's bearded, ·86; Kessingland red, ·92; Nursery red, ·76; Trump white, ·81; Red rivet, 1·00; Lammas red, ·89; Hunter's white, ·75. And different ears of a given variety of wheat have grains of different weight. If six or eight culms come up on one stool, the largest ears have the heaviest grains. In general, the larger flower-cups in an ear, contain the heavier grains. Then, there is scarcely such a thing to be found as a crop of one pure variety. Any variety rapidly gets mixed with others. And, supposing that a plot were set aside for a pure variety, year after

year, for a few cycles of sun-spots, the mineral conditions would be constantly varying; so that any test by the balance to compare the fruit of one year with that of another, would involve too many unappraisable elements to have a real value.

Prof. Jevons observes that his investigation is "embarrassed by the fact that no inquirer has been able to discover a clear periodic variation in the price of corn." But the quality of corn must be a more immediate effect of solar action than the price. Now, although perhaps not much is to be arrived at from the method suggested by Mr. Kemp, there is another direction in which something might be found, and in which the necessary data already exist. I allude to the records of those Corn Exchanges which contain full details of the measure-weight of every parcel of grain which has been sold in them for several sun-spot periods. I reduced the sales in the Haddington Corn Exchange for the year from July 3, 1868, to June 25, 1869, and found the average bushel-weights as under:—

Wheat ...	27,764 quarters	63·15 lbs. per bushel.
Barley ...	33,022 ,, ...	56·85 ,, ,,
Oats	16,223 ,, ...	43·49 ,, ,,

The sales in the Edinburgh Corn Exchange from November 4, 1868, to October 27, 1869, gave the following weights:—

Wheat ...	27,322 quarters	62·84 lbs. per bushel.
Barley ...	35,752 ,, ...	56·18 ,, ,,
Oats	53,843 ,, ...	42·28 ,, ,,

Reductions on this larger scale probably eliminate most of the elements of uncertainty. The measure-weight of the cereal grains depends on various factors, one of which is the comparative distension of the epicarp by the inclosed albumen. It is this element which may vary with variations of solar radiation. And if a cycle of measure-weight should be found corresponding with the sun-spot period, a clue might be gained to some unsuspected commercial relationship.

North Kinmundy, Aberdeen A. STEPHEN WILSON

Time and Longitude

I HAVE been much amused at the questions on the above (NATURE, vol. xviii. p. 40), by Mr. Latimer Clark, and the answer (p. 66) by my old friend Capt. J. P. Maclear; the numbers of NATURE for May having only just reached my "out-of-the-world" residence. I suspect Mr. L. C. has had in his mind what I have often had, and with which I have frequently puzzled some "unco guid" Sabbatarians! If it is such a deadly sin to work on Sunday, one or the other of A and B coming, one from the east, the other from the west, of 180° meridian, must, if he continues his daily avocations, be in a bad way! Some of our people in Fiji are in this unenviable position, as the line of 180° passes through Loma-Loma!

I went from Fiji to Tonga in H.M.S. *Nymph*, and arrived at our destination on *Sunday*, according to our reckoning from Fiji, but *Monday*, according to the proper computation west from Greenwich. We, however, found the natives all keeping Sunday. On my asking the missionaries about it they told me that the missions to that group and the "navigators," having all come from the *eastward*, had determined to observe their *seventh* day, as usual, so as not to subject the natives to any future puzzle, and agreed to put the dividing line further off, between them and Hawaii, somewhere in the broad ocean, where there were no metaphysical natives or "intelligent Zulus" to cross-question them! E. L. LAYARD

British Consulate, Noumea, New Caledonia

Hereditary Transmission

I HAVE perused with interest Mr. Edmund Watt's account of the six-fingered family in Dominica, as it recalls to my memory a family showing precisely the same peculiarities in Ceylon, at Point Pedro, the most northerly point of the island, where, twenty-six years ago, I was magistrate.

A family quarrel came before me, and I found, to my great astonishment, that plaintiff and defendant, and all the witnesses, had six fingers on each hand and six toes on each foot! The additional finger or toe was, in each instance, a "little finger" (or toe) inserted in the side of the hand or foot, quite loosely, adhering to the skin, and not part of the skeleton. It might easily have been excised with a pair of ordinary scissors. The parties were all closely related—brothers and sisters, uncles and aunts, nephews, nieces, and cousins—they must have had a common progenitor. It would be easy, and most interesting, to ascertain if any of the family now exist, and, if so, if the supplementary finger has been transmitted to the present generation. A note to the "Resident Magistrate," Point Pedro, would, I hope, produce a reply. If any of the family of my old clerk, Mr. Dehoedt, survive, they would recollect the fact. I think the party came from Panditerripu. E. L. LAYARD

British Consulate, Noumea

"Survival of the Fittest"

IN NATURE, vol. xix. p. 155, Mr. S. F. Clarke's observations on the cannibal habits so rapidly developed by the larvæ of the New England salamanders are cited in illustration of the survival of the fittest. The fact that similar tendencies are invariably betrayed very early in life by the young of the common Mexican Axolotl (*Siredon mexicanum*), numbers of which are annually hatched out in the Brighton Aquarium, may perhaps be of interest. Many of the smaller and weaker ones are bodily devoured by their stronger brethren of the same brood, an inclination which is so marked that systematic over-feeding is resorted to in order to arrest the diminution in the number of specimens.

Brighton, December 27, 1878 A. CRANE

Shakespeare's Colour-Names

IN the very interesting articles and correspondence which you have published on the subject of colour-blindness, it is rather surprising that no one has referred to a passage which, if taken alone, would appear to show that Shakespeare did not know the difference between green and blue. In "Romeo and Juliet" (Act iii., Scene 5), the Nurse says to Juliet, speaking of Paris:—

> "Oh, he's a lovely gentleman;
> Romeo's a dish-clout to him; an eagle, madam,
> Hath not so green, so quick, so fair an eye
> As Paris hath."

What is here called a green eye is evidently what we call a blue one. But Iago ("Othello," Act iii., Scene 3) calls jealousy a "green-eyed monster," using the expression "green-eyed" as a modern might use it, and meaning something very unlike "blue-eyed." These instances appear only to show that in the language of Shakespeare's time the names of colours were used somewhat vaguely. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, co. Antrim, December 23

DISCUSSION OF THE WORKING HYPOTHESIS THAT THE SO-CALLED ELEMENTS ARE COMPOUND BODIES[1]

I.

IT is known to many Fellows of the Society that I have for the last four years been engaged upon the preparation of a map of the solar spectrum on a large scale, the work including a comparison of the Fraunhofer lines with those visible in the spectrum of the vapour of each of the metallic elements in the electric arc.

To give an idea of the thoroughness of the work, at all events in intention, I may state that the complete spectrum of the sun, on the scale of the working map, will be half a furlong long; that to map the metallic lines and purify the spectra in the manner which has already been described to the Society, more than 100,000 observations have been made and about two thousand photographs taken.

In some of these photographs we have vapours compared with the sun; in others vapours compared with each other; and others again have been taken to show which lines are long and which are short in the spectra.

I may state in way of reminder that the process of purification consisted in this: When, for instance, an impurity of manganese was searched for in iron, if the longest line of Mn was absent, the short lines must also be absent on the hypothesis that the elements are elementary; if the longest line were present, then the impurity was traced down to the shortest line present.

The Hypothesis that the Elements are Simple Bodies does not include all the Phenomena

The final reduction of the photographs of all the metallic elements in the region 39-40—a reduction I

purities is not sufficient. I shall show in detail in a subsequent paper the hopeless confusion in which I have been landed. I limit myself on the present occasion to giving tables showing how the hypothesis deals with the spectra of iron and titanium.

We find short line coincidences between many metals the impurities of which have been eliminated or in which the freedom from mutual impurity has been demonstrated by the absence of the longest lines.

Evidences of Celestial Dissociation

It is five years since I first pointed out that there are many facts and many trains of thought suggested by solar and stellar physics which point to another hypothesis—namely, *that the elements themselves, or at all events some of them, are compound bodies.*

In a letter written to M. Dumas, December 3, 1873, and printed in the *Comptes Rendus*, I thus summarised a memoir which has since appeared in the *Philosophical Transactions*.

"Il semble que plus une étoile est chaude plus son spectre est simple, et que les éléments métalliques se font voir dans l'ordre de leurs poids atomiques.[1]

"Ainsi nous avons :

"1. Des étoiles très-brillantes où nous ne voyons que l'hydrogène, *en quantité énorme*, et le magnésium ;

"2. Des étoiles plus froides, comme notre Soleil, où nous trouvons :

$$\mathrm{H} + \mathrm{Mg} + \mathrm{Na}$$
$$\mathrm{H} + \mathrm{Mg} + \mathrm{Na} + \mathrm{Ca}, \mathrm{Fe}, \ldots ;$$

dans ces étoiles, pas de métalloïdes ;

"3. Des étoiles plus froides encore, dans lesquelles *tous les éléments métalliques sont* ASSOCIÉS, où leurs lignes ne sont plus visibles, et où nous n'avons que les spectres des métalloïdes et des composés.

"4. Plus une étoile est âgée, *plus l'hydrogène libre disparaît;* sur la terre, nous ne trouvons plus d'hydrogène en liberté.

"Il me semble que ces faits sont les preuves de plusieurs idées émises par vous. J'ai pensé que nous pouvions imaginer une '*dissociation céleste*,' qui continue le travail de nos fourneaux, et que les métalloïdes sont des composés qui sont dissociés par la température solaire, pendant que les éléments métalliques monatomiques, dont les poids atomiques sont les moindres, son précisément ceux qui résistent, même à la température des étoiles les plus chaudes."

Before I proceed further, I should state that while observations of the sun have since shown that calcium should be introduced between hydrogen and magnesium for that luminary, Dr. Huggins' photographs have demonstrated the same fact for the stars, so that in the present state of our knowledge, independent of all hypotheses, the facts may be represented as follows, the symbol indicating the spectrum in which the lines are visible.

Hottest Stars	Lines of	H + Ca + Mg
Sun ...	Lines of	H + Ca + Mg + Na + Fe
Cooler Stars	Lines of	— — Mg + Na + Fe + Bi + Hg
Coolest ...	Fluted bands of	— — — — — — Metalloids

Following out these views, I some time since communi-

[1] This referred to the old numbers in which Mg = 12, Na = 23.

cated a paper to the Society on the spectrum of calcium, to which I shall refer more expressly in the sequel.

Differentiation of the Phenomena to be observed on the Two Hypotheses

When the reductions of the observations made on metallic spectra, on the hypothesis that the elements were really elementary, had landed me in the state of utter confusion to which I have already referred, I at once made up my mind to try the other hypothesis, and therefore at once sought for a critical differentiation of the phenomena on the two hypotheses.

Obviously the first thing to be done was to inquire whether one hypothesis would explain these short line coincidences which remained after the reduction of all the observations on the other. Calling for simplicity' sake the short lines common to many spectra *basic lines*, the new hypothesis, to be of any value, should present us with a state of things in which basic molecules representing bases of the so-called elements should give us their lines, varying in intensity from one condition to another, the *conditions* representing various compoundings.

Suppose A to contain B as an impurity and as an element, what will be the difference in the spectroscopic result?

A in both cases will have a spectrum of its own;

B as an impurity will add its lines according to the amount of impurity, as I have shown in previous papers.

B as an element will add its lines according to the amount of dissociation, as I have also shown.

The difference in the phenomena, therefore, will be that, with gradually increasing temperature, the spectrum of A *will fade*, if it be a compound body, as it will be increasingly dissociated, and it *will not* fade if it be a simple one.

Again, on the hypothesis that A is a compound body, that is, one compounded of at least two similar or dissimilar molecular groupings, then the longest lines at one temperature will not be the longest at another, the whole fabric of "impurity elimination," based upon the assumed single molecular grouping, falls to pieces, and the origin of the basic lines is at once evident.

This may be rendered clearer by some general considerations of another order.

General Considerations

Let us assume a series of furnaces A . . . D, of which A is the hottest.

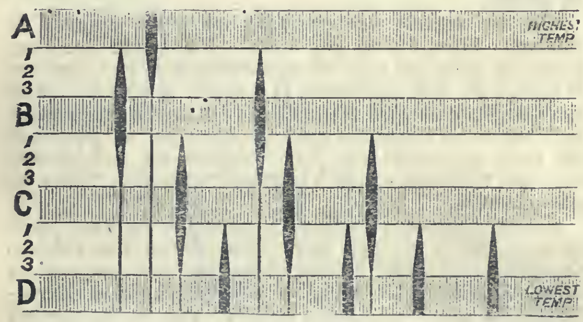

Fig. 1.[1]

Let us further assume that in A there exists a substance α by itself competent to form a compound body β by union with itself or with something else when the temperature is lowered.

Then we may imagine a furnace B in which this compound body exists alone. The spectrum of the compound β would be the only one visible in B, as the spectrum of the assumed elementary body α would be the only one visible in A.

A lower temperature furnace C will provide us with a more compound substance γ, and the same considerations will hold good.

Now if into the furnace A we throw some of this doubly compounded body γ we shall get at first an integration of the three spectra to which I have drawn attention; the lines of γ will first be thickest, then those of β, and finally α would exist alone, and the spectrum would be reduced to one of the utmost simplicity.

This is not the only conclusion to be drawn from these considerations. Although we have by hypothesis β, γ, and δ all higher, that is, more compound forms of α, and although the strong lines in the diagram may represent the true spectra of these substances in the furnaces B, C, and D, respectively, yet, in consequence of incomplete dissociation, the strong lines of β will be seen in furnace C, and the strong lines of γ will be seen in furnace D, *all as thin lines*. Thus, although in C we have no line which is not represented in D, the intensities of the lines in C and D are entirely changed.

In short, the line of α strong in A is *basic* in B, C, and D, the lines of β strong in B are *basic* in C and D, and so on.

I have prepared another diagram which represents the facts on the supposition that the furnace A, instead of having a temperature sufficient to dissociate β, γ, and δ into α is far below that stage, although higher than B.

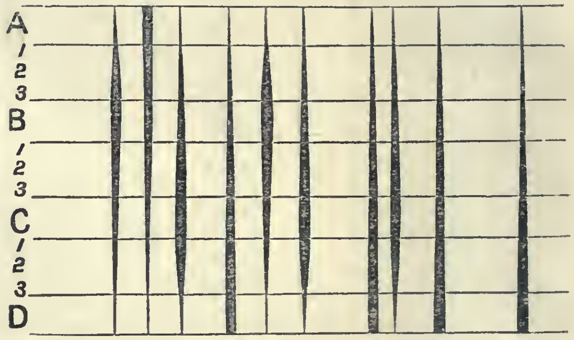

Fig. 2.

It will be seen from this diagram that then the only difference in the spectra of the bodies existing in the four furnaces would consist merely in the relative thicknesses of the lines. The spectrum of the substances as they exist in A would contain as many lines as would the spectrum of the substances as they exist in D; each line would in turn be *basic in the whole series of furnaces* instead of in one or two only.

Application of these General Considerations to Impurity Elimination

Now let us suppose that in the last diagram (Fig. 2) the four furnaces represent the spectra of say, iron, broken up into different finenesses by successive stages of heat. It is first of all abundantly clear that the relative thicknesses of the iron lines observed will vary according as the temperature resembles that of A, B, C, or D. The positions in the spectra will be the same, but the intensities will vary; this is the point. *The longest lines, represented in the diagram by the thickest ones, will vary as we pass from one temperature to another.* It is on this ground that I have before stated that the whole fabric of impurity elimination must fall to pieces on such an hypothesis. Let us suppose, for instance, that manganese is a compound of the form of iron represented in furnace B, with something else; and suppose again that the photograph of iron which I compare with manganese represents the spectrum of the vapour at the temperature of the furnace D. To eliminate the impurity of iron in manganese, as I have eliminated it, we begin the search by looking for the longest and strongest lines shown in the photograph of iron, in the photograph of manganese taken under the same conditions. I do not find these lines. I

[1] The figures between the hypothetical spectra point to the gradual change as the spectrum is observed near the temperature of each of the furnaces.

say, therefore, that there is no impurity of iron in manganese, but although the longest iron lines are not there, some of the fainter basic ones are. This I hold to be the explanation of the apparent confusion in which we are landed on the supposition that the elements are elementary.

Application of these Considerations to Known Compounds

Now to apply this reasoning to the dissociation of a known compound body into its elements—

A compound body, such as a salt of calcium, has as definite a spectrum as a simple one; but while the spectrum of the metal itself consists of lines, the number and thickness of some of which increase with increased quantity, the spectrum of the compound consists in the main of channelled spaces and bands, which increase in like manner.

In short, the molecules of a simple body and a compound one are affected in the same manner by quantity in so far as their spectra are concerned; *in other words, both spectra have their long and short lines*, the lines in the spectrum of the element being represented by bands or fluted lines in the spectrum of the compound; and in each case the greatest simplicity of the spectrum depends upon the smallest quantity, and the greatest complexity (a continuous spectrum) upon the greatest.

The heat required to act upon such a compound as a salt of calcium so as to render its spectrum visible, dissociates the compound according to its volatility; the number of true metallic lines which thus appear is a measure of the quantity of the metal resulting from the dissociation, and as the metal lines increase in number, the compound bands thin out.

I have shown in previous papers how we have been led to the conclusion that binary compounds have spectra of their own, and how this idea has been established by considerations having for a basis the observations of the long and short lines.

It is absolutely similar observations and similar reasoning which I have to bring forward in discussing the compound nature of the chemical elements themselves.

In a paper communicated to the Royal Society in 1874, referring, among other matters, to the reversal of some lines in the solar spectrum, I remarked[1]:—

"It is obvious that greater attention will have to be given to the precise *character* as well as to the position of each of the Fraunhofer lines, in the thickness of which I have already observed several anomalies. I may refer more particularly at present to the two H lines 3933 and 3968 belonging to calcium, which are much thicker in all photographs of the solar spectrum [I might have added that they were by far the thickest lines in the solar spectrum] than the largest calcium line of this region (4226·3), this latter being invariably thicker than the H lines in all photographs of the calcium spectrum, and remaining, moreover, visible in the spectrum of substances containing calcium in such small quantities as not to show any traces of the H lines.

"How far this and similar variations between photographic records and the solar spectrum are due to causes incident to the photographic record itself, or to variations in the intensities of the various molecular vibrations under solar and terrestrial conditions, are questions which up to the present time I have been unable to discuss."

An Objection Discussed

I was careful at the very commencement of this paper to point out that the conclusions I have advanced are based upon the analogies furnished by those bodies which, by common consent and beyond cavil and discussion are compound bodies. Indeed, had I not been careful to urge this point the remark might have been made that the various changes in the spectra to which I shall draw attention are not the results of successive dissociations, but are effects due to putting the same mass into different kinds of vibration or of producing the vibration in different ways. Thus the many high notes, both true and false, which can be produced out of a bell with or without its fundamental one, might have been put forward as analogous with those spectral lines which are produced at different degrees of temperature with or without the line, due to each substance when vibrating visibly with the lowest temperature. To this argument, however, if it were brought forward, the reply would be that it proves too much. If it demonstrates that the *h* hydrogen line in the sun is produced by the same molecular grouping of hydrogen as that which gives us two green lines only when the weakest possible spark is taken in hydrogen inclosed in a large glass globe, it also proves that calcium is identical with its salts. For we can get the spectrum of any of the salts alone without its common base, calcium, as we can get the green lines of hydrogen without the red one.

I submit, therefore, that the argument founded on the overnotes of a sounding body, such as a bell, cannot be urged by any one who believes in the existence of any compound bodies at all, because there is no spectroscopic break between acknowledged compounds and the supposed elementary bodies. The spectroscopic differences between calcium itself at different temperatures is, as I shall show, as great as when we pass from known compounds of calcium to calcium itself. There is a perfect continuity of phenomena from one end of the scale of temperature to the other.

Inquiry into the Probable Arrangement of the Basic Molecules

As the results obtained from the above considerations seemed to be so far satisfactory, inasmuch as they at once furnished an explanation of the *basic lines* actually observed, the inquiry seemed worthy of being carried to a further stage.

The next point I considered was to obtain a clear mental view of the manner in which, on the principle of evolution, various bases might now be formed, and then become basic themselves.

It did not seem unnatural that the bases should increase their complexity by a process of continual multiplication, the factor being 1, 2, or even 3, if conditions were available under which the temperature of their environment should decrease, as we imagined it to do from the furnace A down to furnace D. This would bring about a condition of molecular complexity in which the proportion of the molecular weight of a substance so produced in a combination with another substance would go on continually increasing.

Another method of increasing molecular complexity would be represented by the addition of molecules of different origins. Representing the first method by $A + A$, we could represent the second by $A + B$. A variation of the last process would consist in a still further complexity being brought about by the addition of another molecule of B, so that instead of $(A + B)_2$ merely, we should have $A + B_2$.

Of these three processes the first one seemed that which it was possible to attack under the best conditions, because the consideration of impurities was eliminated; the prior work has left no doubt upon the mind about such and such lines being due to calcium, others to iron, and so forth. That is to say, they are visible in the spectra of these substances as a rule. The inquiry took this form: Granting that these lines are special to such and such a substance, does each become basic in turn as the temperature is changed?

I therefore began the search by reviewing the evidence concerning calcium and seeing if hydrogen, iron, and lithium behaved in the same way.

(*To be continued.*)

ZÖPPRITZ ON OCEAN CURRENTS

I SEND you a translation by a friend of an important contribution to the theory of ocean currents by Prof. Zöppritz, of Giessen, which has recently appeared in the *Annalen der Hydrographie und Maritimen Meteorologie.* The mathematical part of the subject has been published in the *Annalen der Physik* for April last, a translation of which will be found in the *Philosophical Magazine* for September.

One of the main objections urged against the theory that ocean currents are due to the impulse of the winds is that the winds can, it is alleged, produce only a *surface drift*, whereas many of the currents extend to great depths. I have always maintained that this objection is totally erroneous; that if the surface of the ocean be impelled forward with a constant velocity by the wind or by any other cause whatever, the layer immediately below will be dragged along with a constant velocity somewhat less. The layer underneath this second layer will in turn be also dragged along with a velocity less than the one above it. The same will take place in regard to each successive layer, the velocity of each being somewhat less than the one immediately above it, and greater than the one below it. In this manner the surface velocity may be transmitted downwards to any depth. This conclusion has now been demonstrated by Prof. Zöppritz, in the following paper, to be perfectly correct. JAMES CROLL

Though for a long time the majority of seamen and geographers have firmly held the opinion that the great equatorial ocean currents derived their origin from the trade winds, yet, so far as I know, no attempt has yet been made to treat the physical problem of the propagation of surface-velocities downwards through a very thick stratum of water, with the means presented by the theory of the friction of fluids, as elaborated within the last thirty years. Such an attempt is all the more demanded as many authors have lately denied that surface-forces could set the sea in motion to any considerable depth. At the same time the most groundless assumptions have been set forth as to the depth of such drift-currents.

The essential principle of the theory of the internal friction of fluids is that when a plane stratum of water is moved forward, by any cause, in its own plane with a given velocity, the adjoining stratum cannot remain at rest, but, in consequence of its molecular cohesion experiences an impulse to move in the same direction. And if the velocity of the former stratum be continuous the latter assumes a velocity which tends to approximate constantly to the given velocity. This second stratum now exerts the same influence on a third adjoining stratum that it had to suffer from the first, and sets it in motion in the same direction. The third stratum draws with it in a similar manner a fourth, a fourth a fifth, and so on. The propagation of the velocity is only bounded by the limits of the fluid itself. If these limits consist of a solid plane parallel to the strata, then the propagation of the velocity will cease only at this point, *i.e.*, between the last liquid stratum and the first solid stratum.

The law according to which two neighbouring strata of velocities mutually influence one another has already been demonstrated by Newton, and the accelerating force exerted by the friction has been assumed as independent of the pressure and proportional to the difference of velocity. The later theory of the friction of fluids carries out this fundamental hypothesis as to the propagation of velocity between strata of the same medium which lie at an indefinitely small distance ξ from one another, and have accordingly only an indefinitely small difference of velocity Δ, inasmuch as it makes the acceleration produced by the friction, at the plane in which the strata meet, proportional to the quotient $\Delta : \xi$. The factor k, by which this quotient must be multiplied in order to give the acceleration, is called the *Coefficient of Internal Friction.*

The Newtonian hypothesis can be applied likewise to those parts of the bounding-surfaces of the fluid (where it is in contact with other bodies) which may possess independent motion. Here the acceleration produced by the limiting medium (which may be solid, fluid, or gaseous) is proportional to the difference of velocity which may in this case be finite. The factor of the proportion is called the *Coefficient of External Friction.* If the bounding body is a solid or even a fluid, then the fluid may wet it, that is, the stratum of fluid touching the limiting body may cling so fast to that body as to assume the same velocity. The coefficient of external friction is in this case infinitely great. This is the case between wood and water, glass and water; and, on the other hand, not so between glass and quicksilver.

The theory founded on this simple hypothesis has been subjected to the most varied experimental tests, and has, on the whole, been found to agree with the facts, so that the hypothesis may be regarded as proved.

In order to apply this theory to ocean currents, the simplifying presupposition has been made that the ocean is a mass of fluid contained between two horizontal planes at the distance h from one another, but in other respects unbounded. On the surface of this mass of fluid a wind of uniform strength and direction is acting at all times, while the under-surface wets a solid plane, the sea-bottom, and is therefore always at rest.

We must not, however, look on the action of the moving air on the surface stratum of the water as proceeding according to the Newtonian hypothesis; it will act in this way only so long as the surface remains level.

But the wind produces waves and acts on them according to quite different laws. One fact of experience is available here, viz., that the surface-stratum of the ocean under the influence of a uniform wind, moves in the direction of the wind with a constant velocity dependent on the strength of the wind. If, therefore, we place on the velocity of the water at the surface the condition that it has a value w_0 at all times given, everywhere uniform, and of uniform direction, then the problem of the determination of the internal velocity becomes soluble.

But the simplifying presuppositions here assumed are almost realised in the central equatorial regions of the great ocean; the solution of the problem becomes, therefore, of deep interest.

The following are the chief results of the solution:—

If for an infinitely long time the surface-stratum has been kept at an unchanging velocity, then the whole mass of water is in a steady state of motion, *i.e.*, a state which no longer varies according to the time. The velocity w is then dependent only on the depth x beneath the surface, and diminishes in proportion as the depth increases, till at the bottom it reaches *zero.* This relation is expressed by the formula

$$w = w_0 \frac{h - x}{h}.$$

Naturally it is presupposed that no other causes, *e.g.*, displacing currents, affect the motion of the deeper strata. If these deeper strata are kept by any foreign cause whatsoever in steady motion in a direction exactly opposite to the assumed motion, then at some point between the highest and the deepest strata there lies a plane where the velocity = 0. If this plane lies at the depth h_1, then in the mass which lies above it the velocity follows the formula

$$w = w_0 \frac{h_1 - x}{h_1},$$

and is therefore in the same condition as if the strata that lie beneath were a solid mass.

It is specially noteworthy that the velocity is independent of the coefficient of friction, *i.e.*, that in the

state of motion that prevails after an infinitely long time the distribution of the velocity is the same in a thin fluid like water and in a thick fluid like syrup. In the fixed state of motion the influence of friction is shown by the participation of all the strata in the motion which is imparted from without to the surface alone. Dependence on the coefficient of friction takes place only on the consideration of motions that vary with the time, and affords a measure for the depth of penetration of a surface-impulse within a given time.

The formula which gives the velocity at the depth x of a mass of water originally at rest when for the time t the surface has been kept at a constant velocity w_0, has naturally a less simple form than the formula which was found for steady motions. (The formula is the same as that which determines the propagation of heat in a solid wall whose one side is kept at a temperature $w_0°$, whilst the other remains at 0°.) From this formula results the simple law that any velocity whatever between o and w_0 prevails at different times at depths which are related to one another as the square roots of the times. I have used the formula to compute the time that a point at the depth of 100 metres requires to attain half the surface velocity, *i.e.*, $\frac{1}{2}w_0$. The coefficient of friction of the water was assumed according to O. E. Meyer's determination, at 0·0144, in which centimetres and seconds are the units of calculation. The result was that 239 years are required for the layer of water 100 metres deep to assume the half of the surface velocity. If it be asked what length of time is required for one-tenth of the surface velocity to penetrate to that depth, the answer is 41 years. Accordingly, the same velocities will be attained at a depth of 10 metres after 2·39 and 0·41 years respectively. In a more viscous fluid the resulting numbers would be smaller.

These numbers are well calculated to give an idea of the slow rate at which changes of motion are propagated downwards. For the numbers computed for the propagation of a given surface motion, hold likewise for the penetration of a change of the motion from the surface downwards, whose influence is simply added to the already existing motion. A steady current, therefore, whose velocity diminishes linearly according to the depth, will sustain only an extremely slight alteration (except in the strata nearest the surface) from passing changes of motion that affect the surface, *e.g.* from contrary winds or storms. There will prevail, rather, at every deep-lying point of this current, a mean velocity that changes only very slightly according to the time, and which is determined by the mean velocity at the surface. This latter velocity has the direction of the prevailing wind, according to whose strength it varies by a law that cannot be more accurately settled.

If the surface velocity varies periodically according to the time, as is the case with all winds that depend on seasons and the hours of the day, then, after this periodic state has lasted an infinitely long time, the velocity at all depths is a periodic function of the time of similar period, but such that the amount of variation decreases rapidly according to the depth and that the occurrence of the maxima and minima is delayed proportionally to the depth. At a depth of 10 metres the amount of the yearly oscillation is already diminished to less than $\frac{1}{13}$th; at a depth of 100 metres it is beyond observation; at this depth the velocity is that corresponding to the steady state when the mean annual velocity is given to the surface. When the depths decrease in arithmetical proportion, the amounts of the oscillation decrease in geometrical proportion such that at four depths x_1, x_2, x_3, x_4, which stand in the relation

$$x_4 - x_3 = x_2 - x_1;$$

the amounts D_1, D_2, D_3, D_4 stand in relation

$$D_4 : D_3 = D_2 : D_1.$$

A maximum and the following minimum of the annual oscillation always exist at the same time at a vertical distance of 11·9 metres.

To give a conception of the time that a constant surface-velocity which begins at the time $t = o$ requires, in order to bring the interior of an ocean 4,000 metres deep, which was previously at rest, to the state of steady motion, the following numbers will serve:—After 10,000 years there prevails at the half-depth, *i.e.*, at $x = 2,000$ metres, just the velocity $0·037w_0$. Since, according to the already-stated formula, in the steady state the velocity $0·5w_0$ must prevail at this point, it is easily seen how far the ocean is still removed after 10,000 years from the steady state. After 100,000 years the velocity at the depth stated is already $0·461w_0$, therefore very near the definitive value. After 200,000 years it differs only by two units in the third decimal place.

Among the results we have found, particular emphasis is to be laid on two, which seem more or less to contradict the views which have prevailed up to this time. In the first place, the steady motion arising in the interior of an unlimited stratum of water from an unvarying surface velocity makes itself felt with linearly decreasing velocity down to the bottom. Hitherto the view frequently expressed was, that the influence of surface currents, *e.g.*, the drift caused in the tropical ocean by the trade winds, reached only to very moderate depths. Secondly, it was found that all variations according to time, whether periodic or aperiodic, of the forces acting on the surface, propagate themselves downwards with extraordinary slowness, the periodic in very quickly decreasing amount. Taking both statements together, it follows that the movement of the chief part of a stratum of water exposed to periodically varying surface forces is determined by the mean velocity of the surface, and that the periodic variations are observable only in a comparatively thin surface stratum. From this it is obvious that hitherto the influence of the friction was undervalued in one direction, in so far, namely, as it was believed that its influence need not be considered as penetrating so deep, but in another direction it was overvalued, as too great an influence was wont to be ascribed to friction in respect of the propagation of varying current motions Its effect was also very much overvalued in another point, viz., in respect of the action of a bank on a stream flowing along it. If, I repeat, the whole surface is kept at a constant velocity, then also in the current bounded at the side the distribution of velocity in the steady state is independent of the co-efficient of friction. Beyond that, the influence of the banks on the distribution of velocity is exceedingly slight.

A further result is that two steady currents flowing parallel to one another, but in opposite directions, in a fluid-stratum of constant depth, may very well graze one another without mutual disturbance. Their surface of division is then a vertical plane parallel to their direction in which the velocity 0 prevails, and which, therefore, stands to each current in the relation of a solid bank.

We have already shown numerically how extraordinarily slow the velocity existing at the surface is propagated downwards when the interior was previously at rest. Hence it may be concluded, *vice versâ*, that when every point of the whole mass of fluid has at a given moment a given velocity varying according to the depth, and when from the same moment onwards the surface remains at rest, the effect of this initial state vanishes equally slowly, *i.e.*, the ocean passes into the state of rest with the same slowness with which in the first case the surface-velocity was propagated into the interior. In fact the formulæ show that the times for the increase and decrease of the same fraction of the given velocity are expressed by the same number.

If from some cause or other strong currents had been generated in the ocean, say 10,000 years ago, these

currents would certainly not have as yet disappeared, but would still be the chief agents in determining the movement of the ocean at great depths, supposing that the earth were completely covered by an ocean of the uniform depth of 4,000 metres.

The interruption by continents and islands of irregular form will contribute to weaken the effect of these former states of motion, not so much through the increased friction on the ocean-bed as through the reflex currents, which arise everywhere, crossing and impeding one another. But it must be observed after the above numerical proof of the extremely slow spread of local alterations of motion over the interior mass, that the difficulties of an exact computation must not be shirked, on account of the traditional expression: "Friction quickly uses up all these velocities."

It would be possible to determine by observations whether effects of former movements are still present in the ocean. There would be required for this purpose only comparative current-observations at the most varied depths, to be applied in the central parts of the great equatorial currents and of the region of calms. Yet, however, we dare not hope to be able to detect small remnants of interior motion with the same certainty with which the effect of the former high temperature of the earth, which disappears according to the same law, could be detected by subterranean observation of temperature, were one able to penetrate deep enough with the thermometer into the earth's crust.

The above computations give us also an idea how distant must be the time of the initial state. What a long time, for example, must we imagine the trade winds to have been blowing with their present extent and strength in order to be justified in assuming that the present state of motion of the equatorial currents is steady. For that about 100,000 years are needed, supposing we postulate a mean depth of 4,000 metres and do not take into account the deadening influence of continents and islands which must somewhat diminish that number. Every initial state, whatever it may have been, vanishes finally, and gives way to a steady state, only the time varies which is required to diminish the originally arising velocity to any required degree of smallness.

OUR ASTRONOMICAL COLUMN

The Melbourne Observatory.—The thirteenth official Report of the Board of Visitors of the Melbourne Observatory, with the annual statement of the Government Astronomer, is before us. Mr. Ellery reports that the new building to contain the magnetical and meteorological instruments registering continuously by photography is completed. The staff of the Observatory now consists of the director, with a chief assistant (Mr. White) and three junior assistants. The transit-circle is found to be inadequate for modern requirements, and the Board of Visitors lay stress upon the necessity of providing an instrument of greater pretensions, to enable Melbourne to co-operate effectively with European and American observers; the Sydney Observatory being already in possession of a very superior meridian-instrument, and one having been ordered, it is understood, for the observatory under the direction of Mr. Todd at Adelaide, it is hoped that a new transit-circle may soon be provided for Melbourne, and it is suggested that the necessary appropriation, about 1,200*l.*, might be made in two annual votes, as two years will be required for the completion of the instrument.

The great reflector, though reported to be working satisfactorily, the mirrors retaining an excellent polish, and no marked signs of deterioration being visible, is occasionally subject to trifling derangements of its mechanism. Unfortunately the publication of the work with this instrument, the drawings of nebulæ, has been delayed by the loss of the gentleman who copied the drawings on stone. The drawings, however, now only require printing, and their publication is not likely to be long retarded. Mr. Ellery refers to the miscellaneous observations made during the year to which his report relates (to June 30, 1877), including observations of D'Arrest's comet of short period, determination of positions of stars used by Mr. Gill during his expedition to Ascension, measures of southern double stars and of the polar and equatorial diameters of Mars, and of Saturn's ring. With regard to the use of the great reflector it is mentioned, "Out of 326 available nights 150 were unfitted for observation from unfavourable weather, bright moonlight interfered on 32, while 49 were occupied with visitors, which, together with about 20 nights during which the telescope was under repair, or which were unavailable from other causes, left only 75 nights upon which observations could be made." From the observations made during the year upon 77 of the smaller nebulæ in Sir John Herschel's "General Catalogue," it is gathered that while the actual aspect of many conforms precisely with Herschel's description, others are so considerably changed as to be only recognisable by their position. The only change detected in the great nebula about η Argûs, since the drawing in March, 1875, has been "a break or separation in one of the branches on the preceding side."

Observations of the satellites of Uranus were made on sixteen nights, and on the same number of nights the satellites of Mars (the announcement of the discovery of which had been telegraphed to Mr. Ellery by Sir George Airy) were unsuccessfully sought for; the failure to find these objects with certainty and ease Mr. Ellery considers "somewhat unaccountable," but the reader will hardly need to be reminded that there are other cases where the large reflectors have not proved so adequate for work as the large refractors: sooner or later, at Melbourne or elsewhere, we hope to see a large instrument of the latter class applied to the survey of the southern heavens: the real astronomical work in the northern hemisphere, the more precise micrometrical measures and more delicate observations falling to the task of the practical astronomer, have been, as yet, pre-eminently due to the use of the refractor.

Biela's and Halley's Comets.—There are near approximations between the orbits of these bodies not far from points which were first roughly indicated by Littröw, in a communication to the Vienna Academy in 1854, entitled "Bahnnähen zwischen den periodischen Gestirnen des Sonnensystemes." In heliocentric longitude 39° 25′ (equinox of 1836) the distance between the two orbits is 0·032 (the earth's mean distance from the sun = 1), and in 200° 51′, the distance is as small as 0·011. At the former point the true anomaly of Halley's comet is − 94° 9′, with the elements of 1836, and that of Biela's − 71° 17′; at 200° 51′ the true anomaly of Halley's is + 104° 59′, and of Biela's + 90° 2′; we see then that on the last return of Halley's comet to these parts of space, though its orbit approached so near to that of Biela's, there was no near approximation of the two bodies. It will be remembered that Biela's comet also passes very near to the orbit of Tempel's comet 1866 I., and consequently to the track of the November meteor-stream.

GEOGRAPHICAL NOTES

Among the geographical notes in the January number of the new periodical issued by the Royal Geographical Society we find some interesting information regarding the work to be done by Mr. Keith Johnston's East African Expedition. He is instructed to gather data for constructing as complete a map as possible of the route, and to make all practicable observations in meteorology,

geology, natural history, and ethnology, with the view of rendering as exact as possible the information obtained regarding the region, its inhabitants, and products. As special subjects of investigation he is to observe and note the routes best adapted for future more extensive communication, and to spare no efforts in examining the range of mountains seen by Mr. E. D. Young and by Capt. Elton and his party, at the north-east end of Lake Nyassa, ascertaining their extent and elevation, and the condition of the routes or passes over them. The practicability of constructing a line of telegraph from north to south through the region is also to be inquired into. If Mr. Johnston should succeed in reaching Lake Tanganyika he is directed to pay special attention to facts bearing upon the extraordinary rise in its level in very recent times, as stated by Mr. Stanley. Besides making accurate measurements, Mr. Johnston is recommended to institute inquiries as to whether the rise may not be periodical, or the result of a succession of years of excessive rainfall; but in the event of its proving continuous he is to investigate with care the causes and results of so remarkable a phenomenon. This note is followed by a summary of the survey arrangements of the Afghanistan Expedition, which promise to add much to our knowledge of the unknown tracts of country on our north-west frontier. The information contained in the remaining notes has already been placed before our readers in our own columns. The maps in the present number are those of the Fly River, New Guinea, from Signor D'Albertis' survey, of the Sulimani Mountains, on our Afghan frontier, illustrating an article by Mr. C. R. Markham, and of the routes of the Swedish and Dutch Arctic Expeditions.

THE International African Association at Brussels have recently received intelligence that MM. Wautier and Dutrieux, with 360 porters, had left Mpwapwa on October 15 to rejoin M. Cambier. On October 27 they were at Mvumi, in Ugogo, where a letter from M. Cambier reached them, announcing his arrival at Kasisi, which is two days' march from Urambo, the capital of King Mirambo, of Unyamwesi. They are now travelling in company with M. Broyon, Mirambo's son-in-law, who is said to be taking up a large convoy to Ujiji for the English missionaries, and under his able guidance and advice it may be hoped that they will escape similar misfortunes to those which they have experienced in the past.

INTELLIGENCE has been received at St. Petersburg that Prof. Nordenskjöld's steamer *Vega* is ice-bound on the Siberian coast.

IN the last number of the *Tour du Monde*, M. Alfred Marche, the former companion of M. Savorgnan de Brazza, in his explorations of Western Africa, concludes his admirably illustrated chapters, entitled "Voyage au Gabon et sur le Fleuve Ogooué."

PROF. KIEPERT, the eminent geographer, has recently expressed his opinion regarding the alleged return of the Amu Darya (or Oxus) into its ancient bed, and consequently becoming a tributary to the Caspian instead of the Aral Sea. The Professor remarks that all statements made hitherto, even as far back as those of the old Roman writers, are simple speculations, proving nothing else but merely the existence of a dry river-bed in the direction indicated. He thinks it a matter of course that, in the event of unusual accumulation of water in the Oxus, this bed may be filled with water for many miles' distance, and, during the few centuries for which we possess reliable data this event has happened so often, that the present recurrence need not in any way have given rise to so much talk and discussion.

MR. E. F. IM THURN, of the British Guiana Museum, paid a visit, in October and November last, to the Kaieteur Fall of the Potaro River, for the purpose of testing whether it was rightly described by its discoverer, Mr. Barrington Brown, as "one of the grandest falls in the world," as well as to prove the truth of his (Mr. im Thurn's) idea that such a place ought to be a rich treasure-ground for a collecting naturalist. He professes to be disappointed with the fall because it is neither so high as the Yosemité Fall nor so broad as Niagara. But he visited it when the water was at its lowest volume, and yet, when looking at it from above, he confesses that the fall is one of "splendid and awful beauty." Altogether we infer that Mr. Brown's description is essentially correct, especially when the river is at its fullest. The country on the road to and about the fall is described as of matchless beauty, and evidently it is a splendid field for a naturalist. The fall can be reached with comparative ease in a few days from Bartica Grove.

AT the November meeting of the Russian Geographical Society, Admiral Krusenstern described the results of his journey to Siberia in 1876 to investigate the possibility of connecting the basin of the Petchora with that of the Ob, and thus open a continuous water-way from Europe to Siberia. He reports favourably on the practicability of the scheme. The scientific results of the journey are topographical surveys, levellings of the principal parts of the route, a whole series of astronomical determinations, and a large addition to our knowledge of a region still little known.

THE last number of the *Zeitschrift* of the Berlin Geographical Society contains an elaborate paper by Herr G. Hartung on the formation of valleys and lakes. There is also a valuable paper by the late Saharan explorer, Erwin von Bary, on the character of the vegetation of Aïr; besides a large map of the African river Quanga, the result of the exploration of Herr Otto Schütt. The last two numbers of the *Verhandlungen* of the same Society contain some important papers. Prof. Karsten gives some data on the problem of ocean currents, and Dr. Tietze describes the results of his exploration of the volcanic Mount Demavend, to which we referred in a previous number. Dr. Hartmann has some interesting observations on the distribution of deep-sea animals. It will thus be seen that this Society regards geography as embracing a very wide field of research, and in this respect is a model that might with advantage be followed by other geographical societies.

A COMMITTEE has been formed at Berlin with the object of founding a "Central Union for Commercial Geography and the Furtherance of German Interests in Foreign Countries." The Society hopes to enter into friendly relations with all German and foreign geographical societies.

"BOSNIEN in Bild und Wort," is the title of an interesting work by Amand von Schweiger Lerchenfeld, just published by Hartleben, of Vienna. The geographical publications of this firm are of particular excellence, and the present work is a fair case in point. It contains some twenty charming drawings from the artistic pen of J. J. Kirchner, illustrating the most interesting parts of the province which has played so prominent a part in the past year's history. The text is carefully written, clear, and to the point. Altogether the work is an acceptable addition to geographical literature.

THE MARQUESS OF TWEEDDALE, P.Z.S.

IT is with extreme regret that we have to chronicle the death, after a three days' attack of bronchitis, on the morning of December 29, of Arthur Hay, ninth Marquess of Tweeddale, F.R.S., and President of the Zoological Society of London. Born in 1824, the second son of Field-Marshal the late Lord Tweeddale, K.T., a veteran of the Peninsula and other campaigns of "the Great War," Lord Arthur Hay at an early age entered the army, as befitted the godchild of the grand English

captain, and obtained a commission in the Grenadier Guards. But the ordinary guardsman's life in times of peace was inadequate to his aspirations, and reaching the rank of captain, he was soon after appointed aide-de-camp to Sir Henry (afterwards Lord) Hardinge, then Governor-General of India, and in that capacity accompanied his chief through the ever-memorable campaign of the Sutlej. After the English arms had triumphed in the conquest of the Punjab, Lord Arthur was attached to a mission, the details of which, we believe, have never been made public, to some of the tribes bordering upon our northern frontier, and in discharge of that duty reached places unvisited by any European traveller since the days of Moorcroft. Lord Arthur's services in India and the adjacent countries lasted over several years, in the course of which time his attention was attracted by their rich and little-known fauna, and he not only formed the acquaintance, but assiduously cultivated the friendship of two of the greatest Indian zoologists of the time—Jerdon and Blyth—of whom he became an apt pupil, fishes and birds being particularly the objects of his pursuit. Returning home at length he resumed his regimental duties, and on the outbreak of the Russian war, in 1854, he accompanied the expeditionary force first to Turkey and thence to the Crimea, taking part in the operations which ended in the fall of Sebastopol. Soon after the conclusion of peace he left the army, and his old zoological tastes, which had been growing slack, returned to him more strongly than ever. On the death of his eldest brother, Lord Gifford, he became heir to his father's honours and estates, and assumed the courtesy title of Lord Walden, by which, perhaps, he will be most generally recognised, for under that designation he published the greater part of his contributions to zoology, and under it he succeeded the late Sir George Clerk as President of the Zoological Society, performing the duties of that office with a singular amount of dignity and urbanity. For several years he continued to live in a cottage he had built for himself at Chislehurst, and there he began to form an ornithological library and collection on a scale almost unattempted hitherto in this country, though the collection was supposed to be limited to Indian, or at least Asiatic, specimens. On the death of his father, at a very advanced age, in 1876, Lord Walden inherited the Scottish peerage and estates, and thenceforth his home was mainly the old ancestral seat of Yester, near Haddington, where he entered, with the energy natural to his character, upon the life of an agriculturist; in this respect following the example of his father, who had long since turned his sword into a ploughshare, and had earned the reputation of being one of the most scientific farmers in that part of North Britain, which is the head-quarters of scientific farming.

The late Lord Tweeddale was a frequent and, when occasion required, a powerful writer. Most of his acknowledged communications are to be found in the *Journal* of the Asiatic Society of Bengal, the *Ibis*, and the *Proceedings* and *Transactions* of the Zoological Society, but it is believed that his anonymous contributions to the public press were still more numerous, though these were seldom on scientific topics. He married twice: first, the daughter of the late Count Kielmansegge, for many years the popular Minister of Hanover at this Court, who died in 1871, and secondly, a daughter of Mr. Mackenzie of Seaforth, who survives him.

One word must be said of Lord Tweeddale's generosity. No reasonable project for the advancement of zoology in any of its branches was ever started but he was ready to support it liberally. His loss will be deeply felt by a wide circle of his brother ornithologists, and the Zoological Society will find it very difficult to replace him in its presidency, a post which seems to require a peculiar position of scientific and social rank.

NOTES

WE are happy to state that at the end of the last legislative session the French Central Bureau of Meteorology obtained from the National Exchequer a sum of 120,000 francs, required for the organisation of the services which were decreed in the month of June. A semi-monthly paper will be issued by the Bureau summarising the results of observations during that period. The work of normal schools, which had been suspended during two or three years, will be resumed and published as in former times.

THE French Minister of Public Works has prepared a most important decree, which was signed on December 20 last. For the execution of the great works which have been voted by the French Parliament, an auxiliary corps of Ponts-et-Chaussées engineers has been created. The members of this newly created body will enjoy the same privileges as the government engineers who have been trained at the Polytechnic School. The consequence is that the privileges of that celebrated establishment are practically at an end, and the principle that office should be given to the fittest irrespective of their origin has a fair chance of becoming an axiom of the French administration.

THE first part of a posthumous work by Prof. Poggendorf on the History of Physics has been sent us by Messrs. Williams and Norgate. It will be completed in three parts and will contain much interesting matter collected by the late eminent physicist during his long career as lecturer at the Berlin University. We have also received the first part of the "Publications of the Astrophysical Observatory of Potsdam," containing observations of sun-spots from October, 1871, to December, 1873, by Dr. Spörer.

FROM *Science News* we learn that Mr. Alex. Agassiz left Cambridge (U.S.) on December 1 for a second dredging-trip in the West Indies on the Coast Survey steamer *Blake*. The specimens secured by him are divided among scientific men in Europe and America, who work them up, while many of them go into his own Cambridge collection. This year he will cruise between the Windward Islands and the coast of South America, having spent last winter in the Gulf of Mexico.

THE prominence given to science is a noteworthy feature in the annual summaries for the past year which appear in most of our newspapers.

WE have much pleasure in drawing our readers' attention to the following circular concerning a Society for the Collection of South African Folk Lore. The circular explains itself, and we trust that those of our readers who are interested in the subject will subscribe to the periodical which it is desired to start:—"The existence, among the aboriginal nations of South Africa, of a very extensive traditionary literature, is a well-known fact. Not a few stories forming part of this literature have been written down; and as in some of them terms occur which no longer appear to be used in colloquial language, and the meanings of which are, in many instances, not fully understood, there is no doubt that we meet in them with literary productions of great antiquity, handed down to the present generation in a somewhat similar manner to that in which the Homeric poems reached the age of Pisistratus. But European civilisation is gaining ground among the natives, and within a few years the opportunities for collecting South African folk-lore will be, if not altogether lost, at least far less frequent than they are now. This would be a great loss to 'the science of man,' particularly as there is much which is exceptionally primitive in the languages and ideas of the South African aboriginal races. There are not a few missionaries and other Europeans in South Africa who have ample opportunities for collecting South African folk-lore. Some of

these, however, are not aware of the importance of such collections, and those who are would be greatly encouraged in the task of making them, if a channel for their speedy publication existed. In the hope of contributing towards the collection of South African traditionary literature, a Folk-Lore Society is in course of formation at Cape Town, which already includes members in distant parts of South Africa. The publication of a small periodical every second month is also proposed by the Society. The annual subscription to this periodical will be four shillings, exclusive of postage. Folk-lore intended for publication in it should be accurately written down in the language and words of the narrator, and a translation into English, or some other well-known European language, added. Further information regarding facts illustrative of native life or native literature will also, whenever practicable, be published. Intending subscribers to the projected periodical are requested kindly to send in their names and addresses, stating the number of copies required by them, to the secretary of the South African Folk-Lore Society, care of Miss L. C. Lloyd, Cape Town."

ACCORDING to a report made by Prof. Palmieri an interesting application of the microphone to volcanic phenomena has just been made by Prof. Michele Stefano de Rossi, who during a series of experiments extending over several months and made at his seismic observatory at Rocca di Papa in the Albanese Mountains, has found that the present eruption activity of Mount Vesuvius could be perceived through the microphone even at that enormous distance. Prof. de Rossi, in order to continue his experiments, has recently stayed with Prof. Palmieri at the Vesuvius Observatory, and they have together visited the crater of the Solfatara near Pozzuoli, where the subterraneous work of the volcanic forces became so very evident to the sense of hearing, that a considerable amount of fear was caused amongst those present at the experiments. Prof. de Rossi will publish an account of his researches in his serial *Il Vulcanismo*.

EARTHQUAKES are reported from Seefeld (Tyrol) on December 14 at night, where the shock came in the direction from north to south, and from Luxemburg on December 15 at 11 A.M. where six or seven distinct oscillations were noticed.

NEWS from the American Republic of San Salvador states that the volcanoes of Santa Ana and of Izalco are in eruption. The eruption of the former had been anticipated for some time past (see NATURE, vol. xix. p. 86), and seems to be of particular violence.

"AN English Manufacturer" makes a strong appeal in yesterday's *Times* on behalf of the introduction into this country of the decimal system in weights, measures, and coinage. It is long since we showed the absurdity of our present systems, and the necessity for the introduction of something more scientific. But the "Manufacturer" shows that by our want of any international system, such as prevails among other nations, the trade of this country seriously suffers. We hope this aspect of the question will be urged upon the Government by all interested, and that a much more radical reform will be instituted than what has been attempted in the recent most unsatisfactory Weights and Measures Act.

THE director of the Vienna Geological Institution, Counsellor Franz von Hauer, has been nominated "Officier de l'Instruction publique" by the French Minister of Public Instruction.

M. W. DE FONVIELLE sends us the following details concerning the recent electrical observations at Montsouris Observatory:—Electrical observations are registered regularly at Mont souris seven times a day, according to a proper scale of variations, and with a Thomson electrometer. These observations are made by M. Descroix, under the general direction of M. Marie Davy, the director of the observatory, and the results are recorded daily in the Paris *Temps*. The series from the beginning of the month of December offers some notable peculiarities. The frost in Paris set in on December 7, and from that date to the 22nd there were fifteen days of continued cold. Only once, on the 18th, a thaw was for a few hours imminent, but the snow was not melted in the observatory grounds. During the whole of that period not less than 105 careful readings were taken and registered, but not a single one of these readings exhibited the least negative tendency. The variations were very few, and the sign + was always recorded. This high positive state of tension was observed in spite of a number of variations in the pressure of the air, which was almost always under 760 mm., and sometimes so low that the forecast published by the Bureau Central announced "approaching rainfall." The maximum was on the 19th, during a heavy cold fog; it was so large that the instrument was thrust out of balance, and the record of the number is wanting. The tension then exceeded 200 Daniell cells. From that time the scale of comparison was altered, so that the range of the instrument was enlarged. In consequence of this observation it was suggested that the real thaw, or change of weather would not set in without the previous appearance of negative tension. Instructions were given by M. Marie Davy to test this suggestion by a careful examination of the electrical circumstances attending this lengthened period of unprecedented cold and the future thaw which would put an end to it. The thaw set in in France on the night of December 25-26, at an hour varying according to the circumstances of the several localities. The electrical readings at Montsouris were found positive on the 25th during the whole of the day, but the mean value was greatly diminished, and the readings very unequal. On December 26 at six in the morning, negative readings were taken and registered for the first time since December 7. It must be added that under the circumstances the Thomson electrometer kept at Montsouris is not considered by M. Descroix as exhibiting the exact numerical value of the tension of the air, but merely its kind and the general progress of the phenomenon. This reservation has been made in a correspondence with Signor Palmieri, the director of the Mount Vesuvius Observatory, on the occasion of some strictures passed on the location of the Thomson electrometer used in these observations.

NO general meeting of the Association for the Improvement of Geometrical Teaching will be held in January, 1879. Considerable progress has been made by the sub-committees appointed in January, 1878, and draft syllabuses will soon be submitted to members of the Association.

M. VALENTIN has been snowed up during more than fourteen days in the observatory on the top of the Puy-de-Dome, where he takes the meteorological readings. The telegraph connecting Puy-de-Dome with Clermont laboratories being out of order no telegram has been received from him for a lengthened period. No anxiety is felt for his safety, he having been well furnished with provisions and fuel. A similar accident has befallen General de Nansouty, the director of the Pic du Midi Observatory. His telegraphist having descended to Bagnères was unable to ascend again and the General was left to his fate. As he is rather old and of delicate health heroic efforts were made by the peasantry to reach him, which they did on December 24; the telegraphic line was repaired and telegrams recorded as usual in the *Bulletin International*. General de Nansouty refused to relinquish his post, and he is spending his winter as usual on one of the highest peaks of France.

THE *Neue Wiener Zeitung* states that an electric light has been tried on a locomotive on the Vienna Railway system. The

apparatus was designed by Mr. Whitehead, the inventor of the celebrated torpedo, and is said to have worked satisfactorily.

A CORRESPONDENT writes to us that in looking through some of the drawings and prints, &c., of Old London, belonging to Mr. J. E. Gardner, F.S.A., of Park House, he came upon the following interesting handbill:—

London, 1775

Proposals
for a
Short course of lectures
on
Fossils
by
Emanuel Mendes da Costa.

The course will consist of only
TWELVE LECTURES.
A public Introductory lecture will be given *gratis* to
any one who chuse to come.

To begin *on Wednesday, 7 June, at noon*, at the Author's appartments at a shoemaker's opposite Arundel Street in the Strand and the future Lecture Hours will be determined by the subscribers.

The conditions are
One Guinea the course.
To be paid on Subscribing.
Single lectures at two shillings and sixpence each.

Subscriptions are taken in at Mr. Elmsley's, Bookseller, opposite Southampton St., Strand; Mr. White, bookseller in Fleet-street; Mr. Humphreys, dealer in shells and other curiosities in St. Martin's Lane, near Charing Cross; and by the author at his said appartments.

N.B.—The Introductory lecture will be repeated on
Thursday evening at six o'clock.

IT is proposed to hold an anthropological exhibition at Moscow in the coming summer, together with a general meeting of anthropologists from all parts of the world.

WE have on our table the following works:—"History of the Steam Engine," R. H. Thurston, Kegan Paul and Co.; "Études et Lectures sur l'Astronomie," Camille Flammarion, G. Villars, Paris; "Catalogue des Étoiles Doubles et Multiples," Camille Flammarion, G. Villars, Paris; "Sport and Work on the Nepaul Frontier," "Maori," Macmillan and Co.; "Mathematical Problems," J. Wolstenholme, Macmillan and Co.; "The Fairy-Land of Science," Arabella B. Buckley, E. Stanford; "Das Leben," Philipp Spiller, Gerstmann, Berlin; "Wanderings in Patagonia," Julius Beerbohm, Chatto and Windus; "Natural History of Victoria," Frederick McCoy, Trübner; "Fourth Annual Report of the Imperial Mint;" "Extra Physics and the Mystery of Creation," Hodder and Stoughton; "From Kulja Across the Tian Shan to Lob Nor," Col. N. Prejevalsky, Sampson Low and Co.; "The Heart of Africa," Dr. Georg Schweinfurth, Sampson Low and Co.; "The Philosophy of Science, Experience, and Revelation," John Coutts, F. Pitman; "The Native Flowers and Ferns of the United States," Parts 13, 14, 15, 16, Thomas Mechan, L. Prangola, Boston; "The Principles of Light and Colour," Edwin B. Babbitt, Trübner and Co.

THE additions to the Zoological Society's Gardens during the past week include a White-whiskered Paradoxure (*Paradoxurus leucomystax*) from East India, presented by Mr. W. G. Wilson; a Common Barn Owl (*Strix flammea*), British, presented by Mr. W. Davies; a Common Coot (*Fulica atra*), British, presented by Mr. F. H. O'Donoghue; two Philantomba Antelopes (*Cephalophus maxwelli*) from West Africa, two Egyptian Jerboas (*Dipus ægyptius*) from Egypt, purchased; three River Jack Vipers (*Vipera rhinoceros*) from West Africa, deposited.

CIRCULATING DECIMALS

THE properties of circulating decimals mentioned by Mr. R. Chartres and by Mr. E. P. Toy in NATURE (vol. xviii. pp. 291, 541) are particular cases of very general laws relating to the periods of circulating decimals of which, as they are not stated with any approach to completeness in any work on arithmetic with which I am acquainted, it may be worth while to give a brief explanation.

Consider the process of converting a vulgar fraction into a circulating decimal; take for example $\frac{1}{39}$. The work is—

$$\begin{array}{r} 39)\ 1{\cdot}00\ ({\cdot}\dot{0}2564\dot{1} \\ 78 \\ \hline 220 \\ 195 \\ \hline 250 \\ 234 \\ \hline 160 \\ 156 \\ \hline 40 \\ 39 \\ \hline 10 \end{array}$$

which may be more concisely and better arranged thus:—

$$\begin{array}{rl} 39)\ 1 & ({\cdot}\dot{0} \\ 10 & 2 \\ 22 & 5 \\ 25 & 6 \\ 16 & 4 \\ 4 & \dot{1} \end{array}$$

10, 22, 25, 16, 4 being the remainders and the corresponding quotient figures being written at the side. From this it is clear that—

$$\tfrac{1}{39} = {\cdot}\dot{0}2564\dot{1},\ \tfrac{10}{39} = {\cdot}\dot{2}5641\dot{0},\ \tfrac{22}{39} = {\cdot}\dot{5}6410\dot{2},\ \tfrac{25}{39} = \dot{6}4102\dot{5},$$
$$\tfrac{16}{39} = {\cdot}\dot{4}1025\dot{6},\ \tfrac{4}{39} = {\cdot}\dot{1}0256\dot{4},$$

and the numbers 1, 10, 22, 25, 16, 4 form a cycle such that if we divide any one of them by 39 we obtain the others as remainders in this order, and all the fractions give rise to the same period, though the beginning is made in each case at a different place in the period.

The following are three other divisions arranged in the same manner:—

$$\begin{array}{rl} 39)\ 2 & ({\cdot}\dot{0} \\ 20 & 5 \\ 5 & 1 \\ 11 & 2 \\ 32 & 8 \\ 8 & \dot{2} \end{array} \qquad \begin{array}{rl} 39)\ 38 & ({\cdot}\dot{9} \\ 29 & 7 \\ 17 & 4 \\ 14 & 3 \\ 23 & 5 \\ 35 & \dot{8} \end{array} \qquad \begin{array}{rl} 39)\ 37 & ({\cdot}\dot{9} \\ 19 & 4 \\ 34 & 8 \\ 28 & 7 \\ 7 & 1 \\ 31 & \dot{7} \end{array}$$

The four divisions thus give the values of the periods of the fractions $\frac{1}{39}, \frac{2}{39}, \frac{4}{39}, \frac{5}{39}, \ldots \frac{38}{39}$, *i.e.*, of all the proper fractions in their lowest terms, having 39 as denominator. In this case, therefore, there are four distinct periods, or, say, four periods each containing six figures; one of these, viz., that to which $\frac{1}{39}$ belongs, may be called the leading period.

In general if q be any number prime to 10, and if all the proper fractions in their lowest terms having q for denominator be converted into decimals there will be f periods each containing a digits, and a and f will be connected by the relation $af = \phi(q)$, where $\phi(q)$ denotes the number of numbers less than q and prime to it. If q be a prime, $\phi(q) = q - 1$.

It is to be observed that if we divide r and $q - r$ respectively by q the digits of the periods will in the two cases be complementary, *i.e.*, the sum of each corresponding pair will be 9. Thus in the case of 39

$$\tfrac{1}{39} = {\cdot}\dot{0}2564\dot{1} \qquad \tfrac{2}{39} = {\cdot}\dot{0}5128\dot{2}$$
$$\tfrac{38}{39} = {\cdot}\dot{9}7435\dot{8} \qquad \tfrac{37}{39} = {\cdot}\dot{9}4871\dot{7}$$

and $9 + 0 = 9$, $7 + 2 = 9$, &c. Also, the sum of each pair of corresponding remainders is q; *e.g.*, in the divisions for $\frac{1}{39}$ and $\frac{38}{39}$, $\frac{2}{39}$ and $\frac{37}{39}$, the sum of each pair of corresponding remainders is 39.

If, as in the case of 39, the remainder $q - 1$ does not belong to the leading period, the periods may be arranged in pairs, the periods in each pair being complementary to one another. If

the remainder $q - 1$ does belong to the leading period, each period will contain an even number of digits, and the first half and second half of each period will be complementary. Thus, for $q = 73$ there are nine periods: $\dot{0}136\ 986\dot{3}$, $\dot{0}273\ 972\dot{6}$, $\dot{0}410\ 958\dot{9}$, &c., and in each the two halves are complementary. If there is but one period corresponding to q, of course the remainder $q - 1$ must belong to this period, so that in this case the two halves are always complementary. Returning to the period of $\frac{1}{39}$, we see that it is such that if we multiply it by 4 we obtain the same period, only beginning with the last digit, that if we multiply it by 16 we obtain the same period beginning with the last digit but one, and so on. Thus, from knowing that the last figure of the period is $\dot{1}$, and that the last remainder is 4, we can obtain the period; for $4 \times 1 = 4$ so that the last figure but one must be 4, the last two figures must therefore be 41, multiply this by 4 we have 164, so that the previous digit must be 6, and so on. This process amounts to multiplying the 1 by 4, multiplying the 4 by 4, giving 6 and 1 over, multiplying the 6 by 4 and adding the 1, giving 25, *i.e.* 5 with 2 over, and so on, until the period is completed.

In general, in converting $\frac{1}{q}$ into a circulating decimal, if k be the last digit of the period, and r the last remainder $10r - 1 = kq$, so that the last remainder $= \frac{1}{10}(kq + 1)$ and $k = 9, 3, 7$ or 1 according as q ends in 1, 3, 7, or 9. This is, in fact, the property mentioned by Mr. Chartres and Mr. Toy; the class of relations to which it belongs, and the reason for their existence, is evident from what has been said above.

The most direct manner in which the foregoing principles can be applied to abbreviate the labour of division does not consist in multiplying the digits by the remainder from the end but from the beginning. For example, in finding the decimal equivalent to $\frac{1}{17}$ the first four digits are $\cdot 0588$ and the remainder is 4; therefore $\frac{1}{17} = \cdot 0588\frac{4}{17}$, multiplying by 4, we have $\frac{4}{17} = \cdot 2352\frac{16}{17}$ whence $\frac{1}{17} = \cdot 05882352\frac{16}{17}$; we could then find the next four digits by multiplying the four digits last found by 4 and reducing the fraction $\frac{64}{17} = 3\frac{13}{17}$, so that the next multiplication would be a multiplication of the whole period already found by 13; but as in this case the remainder does not recur after eight digits (if it did recur after eight digits the remainder would be $\frac{1}{17}$ not $\frac{16}{17}$), it must consist of sixteen digits, and the next eight are the complements of the first eight, and are therefore 94117647.

The principle of the method is to continue the division till a relatively small remainder occurs and then to multiply the figures already found by this remainder, and so on continually till all the figures are obtained. This is the method that has been generally employed in finding the reciprocals of large numbers when the whole period was required. There are several points to be attended to in order that the process may be simplified as much as possible, but these I pass over. The greatest saving of labour afforded by the principle is when a 5 or 2 occurs as remainder early in the division, as then we obtain all the remaining digits as fast as the hand can write them by division by 2 or 5 in the respective cases, without the occurrence of any fractions. Thus, for example,

$$\frac{1}{61} = \cdot\dot{0}1639344262295$$
$$0819672131147540983606557377049180327868852459\dot{} ;$$

if we perform the division till we come to the quotient digit 5 we then have a 5 remainder, and all the other digits are obtained by halving the figures from the commencement, viz., 1639. . . . The quotient can also be completed rapidly by division whenever a remainder occurs that is a submultiple of one that has previously occurred. Thus in the case of $\frac{1}{61}$, the remainder after the first 6 is 24 and after the first 8 is 12, so that the figures that follow the 8, viz., 1967 . . ., are obtained at once by halving those that follow the 6, viz., 3934. . . .

In the *Messenger of Mathematics* for April, 1878, I published the following note:—

"Write down a 5, divide it by 2 giving 2 with 1 over, divide 12 by 2 giving 6, divide 6 by 2 giving 3, divide 3 by 2 giving 1 with 1 over, divide 11 by 2 giving 5 with 1 over, divide 15 by 2 giving 7 with 1 over, and so on till the figures repeat. We thus obtain the figures 52631578947368421, and these with a cipher prefixed are the period of $\frac{1}{19}$, viz.—

$$\frac{1}{19} = \cdot\dot{0}52631578947368421\dot{}.$$

"If we start with 50 and halve in the same manner, prefixing two ciphers, we obtain the period of $\frac{1}{199}$, viz.—

$$\frac{1}{199} = \cdot\dot{0}05025125628140703517587939698492462311557788944723618090452261306532663316582914572864321608040201\dot{}.$$

"Similarly, if we start with 500 and halve as before, we obtain, after prefixing three ciphers,—

$$\frac{1}{1999} = \cdot\dot{0}005002501250625312656328164082041020510 \ldots,$$

and, generally, the process gives the reciprocal of 1 followed by any number of 9's.

"If we start with 20, 200, 2000, &c., and divide continually by 5 instead of by 2, prefixing one, two, three, &c., ciphers, we obtain the periods of the reciprocals of 49, 499, 4999, . . . For example,—

$$\frac{1}{49} = \cdot\dot{0}2040816326530612244897959183673469387755\dot{1}$$
$$\frac{1}{499} = \cdot\dot{0}02004008016032064128256513026052104208 4 \ldots.$$

"The process is very expeditious, the figures of the periods being obtained as fast as the hand can write them."

The results stated in this note were obtained as follows: the object was to find the divisors for which the first remainder was 5, so that the halving should begin from the first significant figure; these numbers are seen at once to be 19, 199, 1999 . . . Similarly the first remainder is 2 for the divisors 49, 499, 4999 . . . It should be mentioned that these are particular cases of Mr. Suffield's method of synthetic division.

If q be prime and there be only one period corresponding to q (as is the case for $q = 7, 17, 19, 23, 29, 47, 49, 59, 61, 97$, &c.), the $q - 1$ fractions $\frac{1}{q}, \frac{2}{q}, \ldots \frac{q-1}{q}$ have all the same period, viz., the $q - 1$ digits that form the period of $\frac{1}{q}$ are such, that if we multiply them by $2, 3, 4, 5 \ldots q - 1$, we always reproduce these same digits in the same cyclical order, but beginning at a different place. The case of the period of 7, viz., 142857, which is such that, multiplying it by 2, we have 285714, by 3 we have 428571, &c., is well known, and is often given as a puzzle; but the general result is a very remarkable one, *e.g.*, it is remarkable that it should be possible to write down 96 digits, such that their first 96 multiples should consist of the same digits in the same cyclical order. In the foregoing remarks I have confined myself entirely to the statement of the principles connected with the results referred to in NATURE, and to those which arise directly from them.

J. W. L. GLAISHER

SCIENTIFIC SERIALS

American Journal of Science and Arts, December, 1878.—In the opening paper Gen. Warren considers that the Minnesota Valley and the Mississippi Valley above the Ohio have been, as a rule, formed since the deposition of the glacial drift, which exists in the banks of the river, and that the Winnipeg basin drained out southward along it; also, that the loess deposits extending up to the neighbourhood of Savannah are later than the last glacial drift, &c. The hypothesis of southern elevation and northern depression (probably reversed sometimes and repeated) is relied on to explain the effects.—Prof. Dana, continuing his valuable paper on some points in lithology, contends for basing distinction in *kinds* of rocks on difference in chemical and mineral constitution as regards chief constituents, and offers a classification in eight divisions.—The principle that when the entropy of any isolated material system has reached a maximum the system is in a state of equilibrium, is developed by Mr. Gibbs as a foundation for the general theory of thermodynamic equilibrium.—Mr. McGee distinguishes crania of the mound-builders of the Mississippi Valley from those of modern Indians by a greater development of the posterior molars.—An interesting paper by the Rev. C. Hovey, on discoveries in western caves, describes, *inter alia*, the remarkable acoustic properties of Echo River passage-way (in the Mammoth Cave), where a strong vocal impulse is prolonged with sustained vigour for fifteen seconds or more; also a locality discovered last April in the Wyandot Cave, in which "pits, miry banks, huge rocks, are overhung by galleries of creamy stalactites, vermicular tubes intertwined, frozen cataracts, and all, in short, that nature could do in her wildest and most fantastic mood." There is a row of musical stalactites, very broad and thin, on which a chord can be struck, or a melody played by a skilful hand.—Prof. Harrington analyses the Chinese official almanac, issued annually in Decem-

ber, and consisting of two parts, an astronomical and an astrological.

The Journal of the Russian Chemical and Physical Societies of St. Petersburg (vol. x. No. 8) contains the following papers:—On the chlorides of benzol, by Th. Beilstein and A. Kourbatoff.—On the preparation of glycol, by S. Stempnevsky.—On allyl-dipropylcarbinol, by P. and A. Saytzeff.—On pseudopropyl-acetylene, by F. Flavitzky and P. Kriloff.—Remarks by F. Flavitzky on M. Eltekoff's paper on the action of water upon the chlorides of ethylenes and similar compounds in the presence of oxide of lead.—Observations on nitrophenols, by M. Goldstein.—On the nature and the derivates of cholesterine, by M. Valitzky.—On the neutral products of the oxidation of cholesterine, by P. Latschinoff.—On the polarisation of electrolytes, by R. Colly.

SOCIETIES AND ACADEMIES

London

Royal Society, December.—"Note on the Influence exercised by Light on Organic Infusions," by John Tyndall, D.C.L., F.R.S., Professor of Natural Philosophy in the Royal Institution.

Early last June I took with me to the Alps fifty small hermetically sealed flasks containing infusion of cucumber, and fifty containing turnip infusion. Before sealing they had been boiled for five minutes in the laboratory of the Royal Institution, They were carefully packed in sawdust, but when unpacked the fragile sealed ends of about twenty of them were found broken off. Some of these injured flasks were empty, while others still retained their liquids. The eighty unbroken flasks were found pellucid, and they continued so throughout the summer. All the broken ones, on the other hand, which had retained their liquids, were turbid with organisms.

Shaking up the sawdust, which I knew must contain a considerable quantity of germinal matter, I snipped off the ends of a number of flasks in the air above the sawdust. Exposed to a temperature of 70° or 80° F., the contents of all these flasks became turbid in two or three days.

The experiment was repeated; and after the contaminated air had entered them, I exposed the flasks to strong sunshine for a whole summer's day; one batch, indeed, was thus exposed for several successive days. Placed in a room with a temperature of from 70° to 80° F., they all, without exception, became turbid with organisms.

Another batch of flasks, after having their sealed ends broken off, was infected by the water of a cascade derived from the melting of the mountain snows. They were afterwards exposed to a day's strong sunshine, and subsequently removed to the warm room. In three days they were thickly charged with organisms.

On the same day a number of flasks had their ends snipped off in the open air beside the cascade. They remained for weeks transparent, and doubtless continue so to the present hour.

I do not wish to offer these results as antagonistic to those so clearly described by Dr. Arthur Downes and Mr. Thomas Blunt, in the *Proceedings* of the Royal Society for December 6, 1877. Their observations are so definite that it is hardly possible to doubt their accuracy. But they noticed anomalies which it is desirable to clear up. On July 10, for example, they found 9 hours' exposure to daylight, 3½ hours of which only were hours of sunshine, sufficient to effect sterilisation; while, on July 29, "a very hot day, with much sunshine," 11 hours' exposure "9 of which were true insolation," failed to produce the same effect. Such irregularities, coupled with the results above recorded, will, I trust, induce them to repeat their experiments, with the view of determining the true limits of the important action which those experiments reveal.

Chemical Society, December 19.—Dr. Gladstone, president, in the chair.—The following papers were read:—Researches on the action of the copper zinc couple on organic bodies, part ix.—Preparation of zinc methyl, by Dr. Gladstone and Mr. Tribe. (During the reading of this paper Dr. Frankland took the chair.) Methyl iodide in contact with the copper zinc couple is converted at the ordinary temperature, in from three to thirty days, into a crystalline mass of zinc methiodide. By distillation zinc methyl is obtained; the yield in one case was 99·27.—Dr. Debus made some remarks on the formula of glyoxylic acid. The author considers the formula of this acid to be $C_2H_2O_3$, in opposition to Perkin, who from quantitative experiments came to the conclusion that the true formula was $C_2H_4O_4$.—Mr. Wills gave a short communication on the production of oxides of nitrogen by the electric arc in air. The author finds that nitric acid was formed in four experiments equivalent to ·54, ·55, ·6, and ·7 gramme per hour, and points out the importance of this observation with reference to the proposed use of the electric light in dwellings.—On the action of alkaline hypobromite on oxamide, urea, and potassium ferrocyanide, part ii., by W. Foster.—On two new hydrocarbons obtained by the action of sodium on turpentine hydrochloride, by Dr. Letts. The principal point in this paper is the fact that the author has obtained a solid hydrocarbon having the formula $C_{10}H_{17}$, which he designates solid turpenyl.—On the formation of baric periodate, by S. Sugiura and C. F. Cross.—On erbium and yttrium, by T. S. Humpidge and W. Burney. The authors wished to determine the specific heats of these metals, but failed to obtain them in coherent masses. They determined the atomic weight of pure erbium to be 171·61.

Meteorological Society, December 18.—Mr. C. Greaves, president, in the chair.—P. Doyle, F.S.S., J. M. Gray, Lord Hampton, G.C.B., M. Jackson, A. Proctor, G. Simpson, and E. C. Tisdall were elected Fellows of the Society.—The following papers were read:—Abstract of the meteorology of the Bombay Presidency, by C. Chambers, F.R.S., communicated by Sir G. B. Airy, K.C.B., F.R.S., Astronomer-Royal.—Experiments with Lowne's anemometer, by Capt. William Watson, F.M.S.—Meteorology of Bangkok, Siam, by J. Campbell, Staff Surgeon, R.N.—Results of meteorological observations taken at Calvinia, South Africa, by Kaufmann I. Marks, F.M.S.

Royal Microscopical Society, December 11.—Dr. C. J. Hudson, vice-president, in the chair.—Mr. John Harrison and Dr. Alabone were elected Fellows of the Society.—Dr. Hudson described a new species of Rotifer, *Oecistes sphagni*, coloured drawings of which were exhibited. He also exhibited a number of beautiful transparent diagrams of rare species of Infusoria which he described seriatim.—Mr. F. H. Ward read a paper on a new microspectroscope without a slit, and described this and other accessory apparatus to the instrument.—Mr. F. Crisp read a paper on Hoffmann's new camera lucida, in which he described this and other recent forms of the apparatus, figures of some being drawn upon the board. Another form of camera lucida, by Dr. Russell, of Lancaster, was described and figured by Dr. Millar, and a description of a new one by Swift was also given by Mr. Ingpen.—Mr. C. Stewart read a short communication from Mr. A. D. Michael announcing the discovery of the male of *Cheyletus venustissimus*. Attention was called to a new glycerine immersion lens received from America, by Mr. Ingpen.—Mr. Beck, in reference to a suggestion for a universal unit of microscopical measurement, gave his decision in favour of divisions of the millimetre, and presented to the Society a micrometer ruled with this, and also in $\frac{1}{1000}$ inch for ready comparison.

Geological Society, December 18, 1878.—Henry Clifton Sorby, F.R.S., president, in the chair.—Rev. Frederick Charles Lambert, Robert Plant, and Ernest Swain were elected Fellows of the Society.—The following communications were read:—On remains of *Mastodon* and other vertebrata of the miocene beds of the Maltese Islands, by Prof. A. Leith Adams, F.R.S. The author recognised the following Maltese formations:—Upper Limestone.—Maximum thickness over 250 feet, passing into a sandy rock, and that into a hard red limestone. Fossiliferous, containing four Brachiopoda, several Lamellibranchs and Gasteropods, and twenty-five Echinodermata (ten being peculiar). Sand Bed.—Maximum thickness about 60 feet, variable in character, characterised by vast abundance of *Heterostegina depressa*; fifteen vertebrata. The Marl Bed.—Maximum thickness over 100 feet, but sometimes almost wholly thinned out. Organic remains rarer than in the sand bed. The Calcareous Sandstone.—Maximum thickness rather over 200 feet. Contains bands of nodules, of which the second is rich in organic remains. Hence come the noted teeth of Squalidæ. Among its invertebrate fauna are many Pecteus, with other Lamellibranchs, Gasteropods, and Brachiopods. Also twenty-two species of Echinodermata. The Lower Limestone.—Maximum thickness over 400 feet. *Scutella subrotunda* and *Orbitoides despansus* are abundant in the upper part, and it is generally fossiliferous. In a nodule-seam in the calcareous sandstone in the Island of Gozo two rather imperfect teeth of a *Mastodon* have been found. Both are penultimate molars. They agree most

nearly with the teeth of *Mastodon angustidens*, but the characters are not sufficiently well preserved to differentiate the species with certainty. The same formation has furnished teeth of a *Phoca*, to which the specific name *rugosidens* has been given by Prof. Owen. Large teeth referable to the Phocidæ are found in the nodule seams of the calcareous sandstone and in the sand bed; the marl bed has also furnished a portion of a jaw. The Woodwardian Museum contains a part of a jaw of *Squalodon*, evidently from a nodule-seam of the calcareous sandstone (found by Scilla circ. 1670). The sand bed and calcareous sandstone have furnished remains of more than one species of *Delphinus*, and large-sized Cetacean vertebræ are found in nearly all the beds, especially the sand bed. *Halitherium* has been obtained from the sand bed, marl bed, calcareous sandstone, lower limestone, and (?) upper limestone. One specimen of *Ichthyosaurus gaudensis*, Hulke, has been furnished by the calcareous sandstone; the same has also furnished *Melitosaurus champsoides*, *Crocodilus gaudensis*, and *Sterrodus melitensis*. *Myliobates toliapicus* and allied species have come from all the deposits except the upper limestone. *Otobates subconversus* from the sand bed and marl. The squalidæ are abundant from all the deposits except the first. There are ten species belonging to the following genera:—*Carcharodon*, *Carcharias*, *Oxyrhina*, *Hemipristis*, *Corax*, *Odontaspis*, *Lamna*. Remains of *Notidanus*, *Platax*, and *Diodon* have also been found.—Dinosauria of the Cambridge greensand, Parts I.-VII., by Prof. H. G. Seeley, F.L.S. F.G.S. The author stated that this paper was founded upon the collection of more than 500 dinosaurian bones preserved in the Woodwardian Museum, for the opportunity of studying which he was indebted to the kindness of Prof. T. McKenny Hughes. He described the conditions under which the specimens occur, and accounted for the apparently worn state of the bones as the results of exposure to the air, and subsequent maceration.—I. Note on the axis of a dinosaur from the Cambridge greensand.—II. On the vertebral characters of *Acanthopholis horridus*, Huxley, from the base of the chalk-marl near Folkestone.—III. On the skeleton of *Anoplosaurus curtonotus*, Seeley.—IV. On the axial skeleton of *Eucercosaurus tanyspondylus*, Seeley.—V. On the skeleton of *Syngonosaurus macrocercus*, Seeley.—VI. On the dorsal and caudal vertebræ of *Acanthopholis stereocercus*, Seeley.—VII. On a small series of caudal vertebræ of a dinosaur, *Acanthopholus eucercus*, Seeley.

CAMBRIDGE

Philosophical Society, November 18.—Prof. Liveing, president, in the chair.—The following communication was made to the Society:—Some results of the two last total solar eclipses, by Dr. A. Schuster. Every scientific investigation passes through a preliminary stage, in which a general survey of the facts is taken, and by means of which the most hopeful line for future inquiry is determined. Eclipse observations may be said to have just passed through that preliminary stage. The present is therefore a fitting time for a general survey of what has been done, and a discussion of what remains to be done. Eclipse observations may be divided into three classes: spectroscopic observations, polariscopic observations, and general observations on the outline and shape of the corona, which can best be carried on by means of good photographs. 1. Spectroscopic observations.—The spectrum of the corona consists: of a continuous spectrum, in which the dark Fraunhofer lines are faintly seen; of the spectrum of hydrogen gas, and of an unknown line in the green. The pressure of a continuous spectrum indicates the presence of solid or liquid particles, and is most likely partly due to matter falling into the sun. During the last eclipse the first systematic attempt to determine the height to which the continuous spectrum extends was made by Prof. Eastman, assisted by Mr. Pritchett. The result was rather remarkable, for although the corona was not equal in intensity in the four directions, the spectrum disappeared nearly at the same distance all round the sun. The importance of obtaining photographs of the spectrum was pointed out. The various attempts that have been made were mentioned, and the result of the Siamese photographs was compared with that of a photograph of the spectrum obtained by Dr. Henry Draper during the late eclipse. The comparison proves that during the late eclipse, the line spectrum was much fainter. All observers agree on this fact, and Prof. Young's opinion, which is decisive on that point, was quoted. The idea of connecting this fact with the minimum of sun-spots through which we are at present passing is obvious. 2. Polariscopic observations.—Polariscopic observations tend to show that close to the sun the polarisation is small, that it increases up to a distance of a few minutes, and then rapidly diminishes. The author has made a calculation as to what the polarisation ought to be, and has come to the result that in whatever way the scattering matter is distributed, as long as it vanishes nowhere, the polarisation ought rapidly to increase with the distance from the sun. The only way to account for the discrepancy between this result and the actual fact is by assuming that as we move away from the sun, more light is reflected in the ordinary way and less light is scattered. Matter falling into the sun and being gradually broken up by the heat would account for all the facts. 3. General outline of the corona.—It has often been remarked that the corona shows an approximate symmetry round the sun's axis. The author supports the view that the greater extension in the direction of the sun's equator is due to meteor streams which approximately circulate in that plane. He quotes in support of this a fact noticed by him during several eclipses, which indicates that a certain departure from this symmetry takes place in such a way that the corona is wider and more extended on one side of the axis than on the other, and he gives evidence that this departure from symmetry takes place in a direction fixed in space. The statement made by several observers that there is a connection between sun-spots and the sun's corona has induced the author to look carefully over photographs and drawings of the corona made during the last eight eclipses. He has found that during this time the general outline has varied gradually and systematically in a cycle corresponding to that of the sun-spots. The following hypothesis, which seems to account for many facts, was brought forward by the author. A meteor stream is circulating round the sun in a very eccentric orbit. A number of meteors in their perihelion passage are falling into the sun, owing to the increased chances of collision amongst themselves, disintegration owing to rise of temperature and entry into the solar temperature. The local increase of temperature caused by the fall must give rise to currents on the surface of the sun, and may give rise to cyclones which we call sun-spots. If the meteors have a period, so that every eleven years an increased quantity passes the perihelion, a greater number of sun-spots would form, and at the same time we should observe a difference in the shape of the corona, which may well be of such a nature as is actually observed. Dr. Schuster also exhibited to the Society Grant's small calculating machine, for the multiplication of eight figures by eight; he explained its construction, and compared it with that of Thomas of Colmar, which is in general use. Grant's machine is much smaller than Thomas's, but does not perform subtraction directly, as is the case with the latter.

BOSTON, U.S.A.

American Academy of Arts and Sciences, December 11, 1878.—Hon. Charles Francis Adams in the chair.—Prof. Alexander Graham Bell presented a paper upon the use of the telephone in tracing equi-potential lines and surfaces. The results of previous observers, especially those of Prof. Adams, were referred to, and Prof. Bell showed that these lines could be traced more readily with a telephone than with a galvanometer. He made use of a steel-band telephone, which could be clasped about the head, leaving the hands free to perform the experiments. In this way the lines were traced in solids and liquids. By the use of metal exploring rods the equi-potential lines could be traced in the earth about one's feet, or in the neighbourhood of metallic deposits, and might lead to the discovery of metallic deposits or peculiarities in the homogenity of the earth.—Prof. John Trowbridge read a paper upon the results of measurements conducted by himself and Prof. W. H. Hill, of the United States Torpedo Station, at Newport, R.I., upon the heat produced by the rapid magnetisation of iron, nickel, and cobalt. The nickel and cobalt contained from $\frac{2}{10}$ to $\frac{5}{10}$ of 1 per cent. of iron, which was inappreciable in the electro-dynamic experiments. The work done was measured in metre grammes, and gave the result that the molecular heating of equal volumes of iron, nickel, and cobalt can be expressed in metre grammes as follows:—Iron = 2381·43, cobalt = 1906·50, nickel = 1112·11.

PARIS

Academy of Sciences, December 16, 1878.—M. Fizeau in the chair.—The following papers were read:—Observations on M. Pasteur's note on alcoholic fermentation, by M. Berthelot. He describes an arrangement he made for effecting simultaneous

hydrogenation and oxygenation of sugar (by electrical means); he notes that there was a slight production of alcohol.—Study of ordinary and compound engines, &c. (continued), by M. Ledieu.—Report on Mr. Wharton's marine compass, with needle of nickel. Its trial in the navy is recommended.—On the reptiles of primary times, by M. Gaudry. This relates to permian fossils found at Autun. In the vertebræ of Actinodon the parts of the centrum, already in great part formed, but not united, indicate the passage of the imperfect vertebrate to the perfect. M. Gaudry refers to two new reptiles, *Pleurononia pellati* and *Euchyrosaurus rochei;* the latter's name indicates the fact of its having been more adroit with its fore-limbs than reptiles of the present.—Reply to M. Sire's observations on a gyroscopic apparatus, by M. Gruey.—On a new phenomenon of static electricity, by M. Duter. He repeated his experiment, with vessels of the same volume, but with different thicknesses of glass. The variations of volume were nearly in inverse ratio of the squares of the thicknesses.—Artificial production of nepheline and amphigene, by the method of igneous fusion and reheating at a temperature near fusion, by MM. Fouqué and Levy.—Third note on vaccinal infection; elaborative *rôle* of the lymphatic ganglions, by M. Raynaud.—The memoir by Sadi Carnot, "Reflexions sur la Puissance motrice du Feu," published in 1824, and regarded as the origination of the new science of thermodynamics, had very little publicity. His brother, M. H. Carnot, has issued a new edition, with notes (hitherto unpublished), which show that S. Carnot foresaw, with much distinctness, the consequences that would result from his ideas. A copy of the work, with the MS., was presented to the Academy.—M. Mouchez presented drawings of heavenly bodies, by M. Trouvelot (United States).—On the solar spots and protuberances observed with the equatorial of the Roman College, by P. Ferrari. Little more than two tables relating to the second half of 1877.—On the summation of series, by M. André.—On elimination, by M. Mansion.—On the different properties of the mode of distribution of an electric charge on the surface of an ellipsoidal conductor, by M. Boussinesq.—On the spectrometric measurement of high temperatures, by M. Crova. Take, as term of comparison, the flame of a moderator lamp, and let it be 1,000 on the (arbitrary) optical scale of temperature. Then measure with the spectrophotometer the ratio of the intensities of two radiations λ and λ' in the source of unknown temperature and in the lamp-flame. The quotient of these two ratios will be above or below 1,000 according as the temperature of the source in question is above or below that of the lamp-flame. M. Crova gives several examples of his measurements, and thinks the method applicable to measuring the temperature of the sun and stars; also of various industrial hearths.—Specific heat and heat of fusion of palladium, by M. Violle.—Influence of temperature on rotatory magnetic power, by M. Joubert. This relates chiefly to flint (regarding which there has been some discrepancy). M. Joubert finds that the rotatory power increases with rise of temperature, and about $\frac{1}{10}$th of its value, in passing from the ordinary temperature to that of fusion. His methods are described. He succeeded also in measuring the rotation in a body under the sole influence of terrestrial magnetism alone.—On the densities and the coefficients of dilatation of liquid chloride of methyl, by MM. Vincent and Delachanal.—On the oxidation of some aromatic derivatives, by M. Etard.—On the nature of certain accessory crystallised products, in industrial treatment of petroleums of Pennsylvania, by MM. Prunier and David. These rank parallel (mostly) with those extracted from coal oils or derivatives by pyrogenation from benzine.—Researches on urea, by M. Picard.—On hæmocyanine, a new substance from the blood of the poulp, by M. Fredericq. This contains copper, and seems to play a similar *rôle* in respiration to the hæmoglobine in vertebrates.—Influence of different colours of the spectrum on development of animals, by M. Yung. The experiments were on eggs of frog, trout, and Lymnea. Violet is the most favourable light, next comes blue, then yellow and white; red and green seem hurtful. Darkness does not prevent development, but retards it.

December 23, 1878.—Explosion of fuze materials, by M. Dupuy de Lome. This relates to a recent accident to M. Zédé when experimenting with a mixture of gun-cotton and nitrate of ammonia. The mode of combustion suddenly changed under a very slight increase in the tension of the gas.—Formation of leaves and order of appearance of their first vessels in Gramineæ, by M. Trecul.—Craniology of the Papuan race, by M. de Quatrefages. A *résumé* of the seventh volume of his and M. Hamy's work, "Crania Ethnica."—Experiments on the movements of liquid molecules of current waves, considered in their mode of action on the progress of ships, by M. de Caligny.—Mr. Norman Lockyer communicated his paper recently read to the Royal Society.—M. Damon was elected free member, in place of the late M. Belgrand.—On a process for measuring with precision the variations of level of a liquid surface, by M. le Chatelier. A point immersed in the liquid is raised gradually till its extremity is tangent to the surface. The moment at which this is passed is indicated by deformations of the liquid surface, and these deformations are observed by means of light thrown on the surface, reflected, and observed with a lens, the focal plane of which passes through the end of the point. So long as the point is under water one sees a circle uniformly illuminated, but immediately the point emerges a black spot appears in the circle. The method gives very delicate measurements, and one application designed is a very sensitive manometer for detecting weak currents of air (as in mines).—On the determination of the imaginary roots of algebraic equations, by M. Farkas.—On the theory of perturbations of comets, by M. Mathieu.—Results of solar observations during the third quarter of 1878, by M. Tacchini. The calm was increased. Of 100 days of observation, 90 were without spots. He thinks the minimum will probably be passed in 1879. In the zones of maximum frequence of the protuberances there is a minimum of the faculæ, and *vice versâ.* There is a difference in distribution of the protuberances at the epochs of maximum and minimum of spots. There were no metallic eruptions or elementary spectra, &c.—On a new thermograph, and on a general method of integration of any numerical function, by MM. Pictet and Cellerier. Knowing the tension of a vapour, one may determine *à priori* the corresponding temperature.—Magnetic rotation of the plane of polarisation of light under the earth's influence, by M. Becquerel. M. Joubert's experiment was a repetition of M. Becquerel's.—On a new phenomenon of static electricity, by M. Duter. He repeated M. Govi's experiment with mercury (which had left doubts), and got contraction as in other cases.—On four singular epochs of the annual course of meteorological elements, by M. Ragona.—Preparation of cobaltocyanide of potassium and some derivatives, by M. Descamps.—Action of trimethylamine on sulphide of carbon, by M. Bleunard. He describes some of the properties of sulphocarbonate of trimethylamine, and its combinations with the mineral acids.—On the chromatic function in the poulp, by M. Fredericq. The changes of colour in the animal's skin are analogous to those produced by the vaso-motors in the human face; they express various emotions, especially anger or fear. The deep coloured phase represents the state of activity of the muscles of the chromatophores; the phase of decoloration, the passive state of retraction of these bodies.—On the excretory apparatus of *Solenophorus megalocephalus*, by M. Poirier. Previous accounts he finds erroneous.—New researches on suspension of the phenomena of life in the embryo of the hen, by M. Dareste. A continuation of his former experiments, but with use of different temperatures. The results were conformable to what he expected.—On the tertiary strata of Britanny.

AMERICAN SURVEYS AND EXPLORATIONS

ATTENTION has frequently been called in these columns to the progress of American exploration. Only a few months ago[1] reference was made to the want of concert among the different surveying expeditions, to the consequent loss of labour and reduplication of work, and to the desirability of consolidating the whole exploratory service under one connected organisation. It is satisfactory to know that an important movement in this direction is now in progress, and that Congress has called in to its assistance the advice of the most eminent scientific authorities in the States.

Readers of NATURE may remember that a few years ago (1874) a discussion was raised in Congress as to the alleged repetition of the survey of the same area of territory by independent expeditions, and that a committee of inquiry was appointed to take evidence on the subject and report. The result of that inquiry was a recommendation that the Engineer Department should be restricted to such surveys as might be necessary for military purposes; but "that all other surveys for geographical, geological, topographic, and scientific purposes should be continued under the direction of the Department of the Interior." It was easy to see from the evidence given before this Committee that a good deal of personal feeling had been evoked by the conflict of interests among the various surveying corps. The Engineer Bureau, in particular, with its well organised military equipment and its just pride in the large amount of exploratory work it had accomplished, seemed to resent the existence of the civilian expeditions as an infringement of its own proper sphere of operations. We may suppose that it was proportionately chagrined by the decision of the Congress Committee.

There was thus no great love between the rival surveyors in the beginning, and heaven seems to have decreased it on better acquaintance. With their plotting and counter-plotting, of which there has, no doubt, been plenty, we have of course nothing to do. Last summer the subject came up again before Congress. Representative Hewitt moved a resolution there, referring the question of the Geological and Geographical Surveys of the Territories for consideration and report by the National Academy of Sciences. It was known that double surveying had been carried on to a large extent, notwithstanding the information elicited and recommendations given by the Congressional Committee of 1874. One officer, indeed, was alleged to have duplicated surveys to the extent of more than 100,000 square miles, at a cost to the public exchequer of nearly half a million of dollars. The object of the resolution in Congress is said to have been to consolidate the power of the military surveys; but certainly nothing could be more impartial and sweeping than the law passed last June. It was to the following effect:—"The National Academy of Sciences is hereby required, at their next meeting, to take into consideration the methods and expenses of conducting all surveys of a scientific character under the War or Interior Department, and the surveys of the Land Office, and to report to Congress, as soon thereafter as may be practicable, a plan for surveying and mapping the territories of the United States on such general system as will, in their judgment, secure the best results at the least possible cost; and also to recommend to Congress a suitable plan for the publication and distribution of the reports, maps, and documents, and other results of said surveys."

[1] NATURE, vol. xviii. p. 694.

The Academy, in accordance with this requirement, appointed a committee to consider the question. The weight of authority of this Committee may be judged from the names of its members: O. C. Marsh, James D. Dana, William B. Rogers, J. S. Newberry, W. P. Trowbridge, Simon Newcomb, Alexander Agassiz. The finding arrived at by such a group of men must command respect all over the Union, as it will on this side of the Atlantic. At a meeting of the Academy held in New York on November 6th, the result of the deliberations of the Committee was presented in the shape of a formal report, which, being approved and adopted, was forwarded to the President of the Senate on the 26th of the same month.

In this Report the various surveys of the public domain are broadly grouped into two divisions: 1. Surveys of mensuration; and 2. Surveys of geology and economic resources of the soil. Each of these divisions is discussed somewhat in detail.

1. Under the first group are included no fewer than five different and independent organisations: 1. The Coast and Geodetic Survey. 2. The surveys carried on by the War Department to the west of the 100th meridian. 3 and 4. The topographical portion of the work carried on by the two surveys under the Interior Department. 5. The survey for land-parcelling under the Land Office. Between these various kindred works no concert or co-ordination of any kind exists. In the language of the Report, "their original determinations of position are independent, their systems of surveys discordant, their results show many contradictions, and involve unnecessary expenditure." On the one hand the geographical reconnaissances of the Engineers and the Interior Department are too sketchy to serve for the subdivision of public lands; on the other hand, the land-parcelling surveys are of correspondingly slight topographical or geographical value. The National Academy insists that as all these surveys must be based upon accurate determinations of position, they can never be effectively and economically conducted until they are united into one system conducted under the same head. On a review of the powers and capabilities of the different surveying staffs, the Academy has come to the conclusion that the Coast and Geodetic Survey is, practically, best prepared to undertake the charge of the unified system proposed to be established. It recommends that this survey be transferred from the Treasury to the Department of the Interior, and that, with its modified and extended functions, it should hereafter be known as the United States Coast and Interior Survey, with a Superintendent appointed by the President, and reporting directly to the Secretary of the Interior. The duties of this branch of the public service, besides those of the present Coast and Geodetic Survey, should include a rigid geodetic survey of the whole public domain; a topographical survey, including detailed topographical work, as well as

rapid reconnaissances like those now carried on by the War and Interior Departments; and, lastly, surveys for the parcelling of public land.

2. Having regard to the enormous area of territory yet to be explored and surveyed, its vast mineral wealth, its agricultural and pastoral resources, its stores of timber, its capabilities of soil, the Academy believes that the best interests of the country require that, for purposes of intelligent administration, a thorough knowledge must be obtained of the geological structure, natural resources, and products of these regions. It therefore recommends the establishment of an independent organisation, with a Director appointed by the President, to be placed under the Department of the Interior, and to be styled the United States Geological Survey. The duties of this Survey would include the investigation of the geological structure and of the economic resources of the public domain.

This consolidation of all the surveying work, sanctioned and paid for by Congress, would of course involve radical changes in some of the Departments. The Bureau of Engineers, in particular, would be required to give up all surveying work except what might be necessary for merely military purposes, and for such engineering operations as the rectification of rivers, irrigation and drainage, reclamation and protection of alluvial land. The various geographical and geological surveys west of the 100th meridian, now carried on by the War and Interior Departments, would be discontinued, though of course they would, in some cases, be resumed under the proposed new organisation.

Three distinct branches of the public service are thus proposed to be established for dealing with the public domain:—First, the United States Coast and Interior Survey, charged with the accurate mapping of the country; second, the United States Geological Survey, for the investigation of the geological structure and natural resources of the domain; third, the Land Office, having charge of the subdivision and sale of the public lands, and entitled, therefore, to call upon the Coast and Interior Survey for all necessary surveys and measurements, and upon the Geological Survey for all information as to the value and classification of lands.

Considerable liberty is proposed to be given to the chiefs of the two surveys as to the nature and extent of their publications. They are each to present an annual report of operations, and provision is to be made for the issue of such maps, charts, reports, discussions, treatises, and other documents as they may deem to be of value. Most liberal provision is likewise recommended to be made for the distribution of the reports of the Surveys. Besides the number of copies required by Congress for its own use, 3,000 copies are proposed to be published for scientific exchanges by the heads of the surveys and for sale. The special reports are to be issued in uniform quarto size, liberty being left to each director to choose such a form for his chartographic publications as shall combine the most effective style with the greatest economy. All specimens collected by the two surveys when no longer required for the investigations in progress are to be transferred to the National Museum.

Such in brief are the recommendations made by the National Academy in response to the requirement of Congress. That they are eminently wise and thoroughly practicable must be freely admitted by all capable of forming an opinion on the subject. It is simply impossible that things can go on as they are. Each one of the Surveys now in progress has done good work; several of them most admirable work. But work as good could be got with less labour and at less cost. This cannot be effected without combination; and the Academy has pointed out with great clearness and judgment how the combination may be achieved. It is not to be expected that changes of this kind can be carried out without irritating some of the individuals whose position is thereby affected. But save the severance of the Bureau of Engineers from all control of the surveys there need be comparatively little disturbance of the work now going on. Dr. Hayden, who with his staff has done so much in recent years for American geology, would doubtless take a high command under the new system; and it may be hoped that his position will be so secured as to enable him to devote his whole time to the scientific work for which he has shown himself to be so admirably qualified. Mr. Powell and his colleagues might continue their interesting and important Colorado investigations. To Mr. Clarence King fresh fields of research lie open where he may win laurels as bright as those he now wears. To all these officers in so far as they have at present geographical and topographical work to carry on, the allocation of all such duties of mensuration to a special geodetic survey should be a welcome relief, as it will set them free for their own special investigations. The Academy in its Report contemplates the possibility of officers, both of the army and navy, being desirous to volunteer for employment in these surveys, and recommends that when their services are not otherwise required they should be permitted to take part in the general survey. In this way a connection with the engineers might be re-established, and we may be sure that every engineer officer of capacity would be welcome, and would take a good position under the Department of the Interior.

The Report of the Academy, on being presented to Congress, was, on the 2nd ultimo, referred to the Committee on Appropriations, and ordered to be printed. As Congress rises at the beginning of March, some action may be expected to be taken on the matter before that date. It will be a subject for sincere congratulation among all well-wishers of American science and general progress, should the decision be in the direction pointed out by the National Academy of Sciences.

ARCH. GEIKIE

KERNER'S "FLOWERS AND THEIR UNBIDDEN GUESTS"

Flowers and their Unbidden Guests. By Dr. A. Kerner. With a Prefatory Letter by C. Darwin, M.A., F.R.S. The translation revised and edited by W. Ogle, M.A., M.D. (London: C. Kegan Paul and Co., 1878.)

THIS charming book is the record of an extension, in a somewhat different direction, of the researches of Darwin, Hermann Müller, and others, on the assistance rendered by insects in the cross-fertilisation of flowers. Attention has hitherto been directed almost exclusively

to the contrivances by which insects, while feeding on or sucking the honey from the nectary, are almost compelled to be the involuntary agents in the transmission of the pollen from the anther to the stigma in a different flower of the same species. In almost all cases, however, it is only a comparatively small number of insects that would be adapted, by the size of their body, the length of their proboscis, and other points in their structure, to insure the cross-fertilisation of any particular species of flower. It is obvious that the visits of all other insects, which would consume the honey without aiding in the transmission of pollen, not only can be of no advantage, but must be positively injurious to the plant, by preventing the visits of the useful insects. It is this point that Prof. Kerner has studied with great industry and acumen; and he has compiled a number of most interesting illustrations of the contrivances presented in the structure of the flower, which not only force the useful insects to enter it in the particular way which shall be of most advantage to it, but keep out all others.

Dr. Kerner is dissatisfied with the vague use in botanical works of the words "self-fertilisation" and "cross-fertilisation," and proposes to substitute them by others which shall have a more definite meaning. He uses the term "autogamy" for the fecundation of a flower by the pollen from the andrœcium of the same flower; "geitonogamy" for the fecundation of a flower by pollen from other flowers on the same plant; and "xenogamy" for fecundation by the pollen from a flower on another plant; while the term "allogamy" would include the last two as contrasted with autogamy. The only previous attempt at a strict scientific terminology with which I am acquainted is by Delpino,[1] who distinguishes four kinds of fecundation: homoclinic homogamy, fecundation by pollen from the andrœcium of the same hermaphrodite flower; homocephalic homogamy, fecundation by pollen from the andrœcium of a different flower of the same inflorescence; monoicous homogamy, fecundation by pollen from the andrœcium of a flower belonging to a different inflorescence on the same plant; and dichogamy, fecundation by pollen from the andrœcium of a flower on a different plant. Prof. Kerner's terms will at all events be admitted to have the merit of being the simplest, and will probably be generally adopted in future.

It may be stated as a general rule that, while the visits of winged insects are beneficial, those of wingless insects are mostly injurious, since these consume the nectar without immediately afterwards visiting another flower so as to favour allogamy. Hence the majority of the contrivances which Kerner describes are for the purpose of excluding from the flower wingless insects, and in particular ants, the great enemies of flowers, and the aphides which attract ants. The flora of the mountain valleys of the Tyrol furnishes almost inexhaustible material for working out a problem of this kind; and of this material Dr. Kerner, who holds the position of professor of botany in the University of Innsbrück, has availed himself to the full.

Simplest among the contrivances for excluding useless, while admitting useful insects, are the more or less dense collections of hairs which cover up the entrance to the nectary in so many flowers, rendering the road inaccessible to very small insects, while presenting no obstacle to larger insects which can brush them aside or pierce them with their proboscis. Beautiful instances of this arrangement are described and illustrated in the work before us in the cases of *Anchusa arvensis*, *Lonicera alpigena*, *Veronica chamædrys* and *officinalis*, *Malva rotundifolia*, *Monotropa hypopitys*, *Menyanthes trifoliata*, and many others. Sometimes these coverings take the form of appendages to the corolla which protect the openings to the nectaries with flaps, as in *Gentiana nana* and *Soldanella alpina*. Again, access to the nectary by small insects is often prevented by the parts of the flower being bent, dilated, or crowded together, the same contrivances resulting also in forcing those insects which are useful to enter and leave the flower in such a way as to be of the greatest service in the transmission of pollen. Thus, in *Nigella* each spoon-shaped petal is hollowed out into a kind of pit, into which nectar is secreted in abundance. At the point where the handle of the spoon is continuous with the bowl the petal gives off an excrescence which covers in the whole nectar-cavity like a lid, closing it completely, and no insect can possibly rifle the nectar unless it be strong enough to lift up this lid. Ants are by this means entirely excluded, while the common honey-bee is able to lift the lid with ease, in doing which he must inevitably rub against either anther or stigma, according to the stage of development of the flower. In his "Entdeckte Geheimniss der Natur" (1793) Sprengel describes, with wonderful accuracy, the proterandrous flower of *Nigella*, and the mode in which the structure of the various parts secures allogamy by the agency of bees. He observed the flaps over the nectaries, but suggests no other interpretation of them than to serve as a protection against rain. A similar occlusion of the nectary against small insects is effected in *Cynoglossum* by the outgrowths from the mouth of the corolla, in *Campanula* and *Phytemna* by the strap-shaped lower parts of the filaments, in *Ranunculus glacialis* and many Mesembryanthemaceæ and Cactaceæ by the mass of crowded filaments, in *Pentstemon* by the fifth barren stamen.

These protective and prohibitive arrangements are frequently placed, not inside, but outside, the flower, one very common form being the hairs, glandular or not, with which the calyx, bracts, or upper part of the stem are so frequently clothed; and the purpose is still more effectively answered when the glandular hairs or the stem itself exude a viscid secretion. In such plants as *Cistus ladaniferus*, *Listera ovata*, *Geranium sylvaticum*, *Euphrasia viscosa*, *Lychnis viscaria*, and a large number of species belonging to the orders Caryophyllaceæ, Saxifragaceæ, Labiatæ, and Scrophulariaceæ, it is almost impossible for the flower to be visited by any but winged insects. Prof. Kerner believes that the numerous insects which are found adhering to the viscid peduncles and stems of these plants are not digested so as to serve the plant with nutriment, but that the object of their destruction is simply to prevent their reaching and rifling the nectary. An explanation is thus offered of the well-known fact that the same species will frequently assume a hairy habit when growing on land, and a glabrous habit when growing in water, water-plants being almost invariably destitute of hairs. An admirable instance of this

[1] *Nuovo Giornale Botanico Italiano*, vol. viii., 1876, p. 146.

law is furnished by *Polygonum amphibium*. Kerner shows that the nectaries of this plant are entirely unprotected against the incursions of "unbidden guests." When growing in water this is no disadvantage, because none but flying insects can reach the flower. But when growing on land the nectar would be liable to be rifled by small creeping insects that would carry it away without performing any compensating service to the plant, and in such circumstances an innumerable quantity of glandular hairs make their appearance on the epidermis of the leaves and stem which effectually bar the way against the unwelcome visitors. "If the ground on which a *Polygonum* has grown for years in dryness, so as to have become covered with these trichomes, again be flooded, and the stems and peduncles again therefore be encircled with water, the trichomes with their viscidity disappear, and the epidermis again becomes smooth and even." I find this statement difficult to reconcile with a dictum laid down further on in the volume—and, as it appears to me, laid down hastily without sufficient warrant—that "the so-called process of 'adaptation' is never a direct one, never comes simply in response to a want. In other words, external conditions can never occasion an inheritable change of form, whether advantageous or the contrary, can neither determine the development of an organ nor its abortion."

Although glandular hairs or viscid secretions are the most common contrivances for preventing the access to the nectary of useless insects, they are by no means the only ones. The same object is attained by the prickles which cover the upper portion of the stem or the peduncles, and the spines into which the involucre of many Compositæ is converted. The waxy or even the glabrous epidermis in some plants prevents creeping insects from reaching the flowers. Even the latex or milky juice of such orders as Euphorbiaceæ, Convolvulaceæ, and Cichoriaceæ is pressed into the service. Kerner placed various kinds of ants on plants that were full of milky juice, such as the common lettuce. No sooner did they reach the uppermost leaves or peduncles than their feet cut through the tender epidermis of those parts, causing the latex to flow, which immediately glued the little animals to the stem so that they were totally unable to escape, and most of them miserably perished. The extra-floral nectaries, on the leaves or other parts of the plant, of *Viburnum tinus* and *opulus*, *Impatiens bicornis*, and many Leguminosæ, serve a similar purpose of diverting creeping, but not winged insects from the flower; since an insect crawling up the stem would always reach these secretions of nectar before the flower.

Some plants have to be protected from animals of a larger size, ruminants and other herbivorous quadrupeds. Some are altogether so protected by their prickly stem and leaves, or by the nauseous or unwholesome secretions of their tissues. But unpalatable secretions are much more common in the petals than the leaves; and with many plants the leaves are eagerly devoured by grazing animals or by caterpillars, while the flowers are left entirely untouched. While the comparatively large size of the flowers of alpine plants no doubt has for one object the attraction of hymenoptera and lepidoptera from a distance, the large area occupied by them in comparison to the leaves—the very character which renders many of them such favourite ornaments of our rockeries and flower-beds—doubtless also serves to protect them from destruction by goats and other mountain quadrupeds.

Space does not allow me even to refer to many other singular and interesting relationships pointed out by Prof. Kerner. It is of course quite possible that further examination may modify some of his conclusions in their detail. For example his belief that the main object of the viscid secretion on the leaves of *Pinguicula* is to prevent the access of creeping insects to the flower hardly appears consistent with the fact that most species of the genus flower early in the spring, while the secretion continues its activity through the summer and autumn. But the book is a perfect mine of original research, and is indispensable to all who are interested in the many problems connected with the fertilisation of flowers.

Dr. Ogle's translation is, with but little exception, easy and graceful. His editorial notes are useful, and he has adopted the praiseworthy practice—since the work is intended for non-scientific as well as for botanical readers—of explaining in foot-notes the meaning of technical terms used by the writer. In a future edition this practice might with advantage be extended. Such a term as "epiblasteme" does not carry its own meaning with it; and even botanists not well read up in recent literature would be puzzled by it. Or perhaps a glossary would be more useful. Three large-sized lithographic plates crowded with detail add greatly to the lucidity of the descriptions.

ALFRED W. BENNETT

FLAMMARION ON DOUBLE STARS

Catalogue des Étoiles Doubles et Multiples en Mouvement relatif certain. Par Camille Flammarion. (Paris: G. Villars, 1878.)

IN this compact volume of less than two hundred octavo pages M. Flammarion has collected together the large number of measures of double and multiple stars, exhibiting change in the relative positions of the components, which have been made by various observers since the time of the father of double-star astronomy, Sir W. Herschel. Those who have been occupied in the study of this branch of the science will be well aware of the difficulty and trouble attending the preparation of a complete history of any of these objects from the measures being scattered through a great many astronomical works, some of them not always easily accessible, and M. Flammarion has not yet attached his name to any volume which is likely to compare with the present one in usefulness.

The author's authorities are about one hundred in number, and he refers to them by abbreviations, a list of which precedes his catalogue, but it is to be regretted that he has not also prefixed the titles of the volumes whence the various measures have been taken, and the more so as there are indications that the original authorities have not been invariably consulted. Thus a number of Capt. Jacob's measures made with the Lerebours equatorial at Madras and published in the first catalogue in the volume of Observations 1848-52, are omitted in M. Flammarion's lists, though he has others which appear in the second catalogue in the same volume, formed after the substitution of a new object-glass. In the case of π Lupi, where he regrets "que les étoiles australes soient

si négligées," he has omitted all Capt. Jacob's measures subsequent to 1848, and as instances where some measures are wanting, may be mentioned γ Argûs, ρ Herculis, δ Herculis, τ Ophiuchi, 70 Ophiuchi, ε Equulei 61 Cygni, θ Indi, &c., &c.

After exhibiting the measures of each object, M. Flammarion, in the great majority of cases, appends his own conclusions with respect to the cause of the relative changes of position, which have generally been carefully considered, though there are some few in which we should hardly be disposed to follow him. But the reader having nearly all that is known of the different objects before him, in M. Flammarion's summary, will be able to form his own inferences. If an observer he will be guided thereby to a selection of objects most worthy of his attention, or most requiring further measures for the elucidation of the cause of altered position.

In a provisional examination of the volume ample proof is afforded of the care taken by the author in his work, which has no doubt been as he describes it long and laborious. There are a few such oversights as H_2 3678 for H_2 4087; and under Procyon, misled by a measure of Secchi's in 1856 as printed, he refers to a companion at 83°·6 and 33″·16; this measure, however, really belonged to Powell's distant companion, and instead of 33″·16 the distance should be 331″·6, as it is given in another page of the same volume of Memoirs of the Roman Observatory. There is no reference to some of Argelander's determinations of proper motion, as in the case of a distant companion of γ Leonis, upon which M. Flammarion enters into some detail. Omissions like this, however, are perhaps unavoidable in the first preparation of such a work, but the author will doubtless have his attention called to them, and will be able to make his second edition a still more inclusive manual of double-star astronomy, than even this first impression.

Through the kindness of Leverrier, M. Flammarion was allowed the use of one of the equatorials at the Observatory of Paris during the year 1877 for the re-measurement of a number of the double stars; these measures applying to about 130 objects are given at the end of the preface to this volume: amongst them we note the close pair of 40 Eridani, a rapidly revolving star which has not received the attention it deserves from observers.

M. Flammarion's work will doubtless soon find its way into the hands of every one who is interested in the double and multiple stars, and he will certainly experience the satisfaction of receiving the well-earned thanks of many amateurs who have no convenient access to large astronomical libraries and to whom his volume will be a valuable *vade-mecum*.

OUR BOOK SHELF

The Mollusca of the Firth of Clyde; being a Catalogue of Recent Marine Species Found in that Estuary. By Alfred Brown. (Glasgow: Hugh Hopkins, 1878.)

ALTHOUGH the recent mollusca of this district have during the last few years received a good deal of attention, especially from the labours of M'Andrew, Barlee, and Merle Norman, still the various memoirs detailing the results of these labours were only to be found widely scattered through a number of scientific periodicals, and Mr. Brown has in this neatly printed work given us not only a *résumé* of the labours of the naturalists we have referred to, but also of all those who have collected on the Firth of Clyde, and joined these to the labours of Mr. David Robertson and his own. The result is, so far as the testaceous mollusca go, a large and apparently accurate catalogue, which will show not only what has been done but also among the nudibranchs and cuttle-fish what is yet to be done. The notes under the heading of Habitat in this catalogue are often most interesting, giving details not only of the exact localities for the species, but notes also of their local names.

Wanderings in Patagonia; or, Life among the Ostrich-Hunters. By Julius Beerbohm. Map and Illustrations. (London: Chatto and Windus, 1879.)

THE title of this book is somewhat misleading, as the author's "Wanderings" were of a very limited extent, embracing only a small portion of the south-east coast region of Patagonia. Its most important feature is the account given of the life of the ostrich-hunters, and it adds little to our knowledge of Patagonia in addition to what has been told us by Musters and the one or two others who have really "explored" more or less of the wild region. The author's story is pleasant to read.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Tempel's Comet

THE well-known comet- and nebula-finder of the observatory of Arcetri, Tempel, has just made an observation of great interest in reference to his Comet No. II. of 1873, which, as astronomers know, has an orbit between Earth and Jupiter. It has no tail, but a nebular surrounding, which Tempel observed to be gradually diminishing in luminousness without losing bulk, and finally has entirely disappeared, leaving the comet perfectly distinct, but with a slight scintillation or rather an appearance of being composed of several masses having motion in the rest of the nucleus; probably an optical effect due to our own atmosphere, but which is at all events seen quite distinctly enough to make it certain that the disappearance of the nebulous surrounding is not due to failure of the telescope to show it.

The comet was last observed on December 18, at 6h. 53m. 12s. mean time of Arcetri in Right Ascension 23h. 3m. 14·15s., and in South Declination 19° 15′ 54″·8. It was seen on the 21st but briefly, and no observation could be made. Since then the continually cloudy sky has prevented it from being seen, but Tempel is confident of being able to see it through January. It is now amongst the asteroids.

The Cosine Galvanometer

IN NATURE, vol. xix. p. 98, my name appears in a way that might lead the reader to infer that I was the inventor of the "cosine galvanometer." My knowledge of this useful instrument was derived from Prof. Trowbridge, of Cambridge, U.S., who described it in 1871 in the *American Journal of Science*, vol. cii. p. 118. In my "Physical Manipulation" I omitted to mention Prof. Trowbridge's name, supposing that his connection with the instrument was too well known to render it necessary.

EDWARD C. PICKERING

Harvard College Observatory, Cambridge, U.S., December 20, 1878

Force and Energy [1]

II.

IN passing it may be noticed that the plus sign thus deduced for a tensive force is otherwise convenient because tension results in a positive increase of the dimensions in the direction of the tension of the body through which the tension is transmitted.

[1] Continued from p. 196.

With regard now to the investigation of the equilibrium or the acceleration of momentum of a body founded on a knowledge of the forces acting upon it, that is, of the various rates of transference of momentum between it and other bodies through its surfaces, we must evidently give signs to the various surfaces of the body, surfaces which are parallel, and face opposite ways, being given opposite signs. If we multiply the transferences of momentum taking place through the different surfaces each by the sign of the surface through which it takes place, and add all these products together, the sum will be the acceleration of momentum of the body. Thus two equal tensive forces acting through parallel opposite faces would keep the body in balance. Or two numerically equal forces, the one tensive and the other compressive, acting through parallel surfaces facing the same way, would also keep the body in balance. If the phrase "intensity of force" be used to mean the force per unit area through any surface, so that it is simply a generalisation of the two common phrases "intensity of pressure" and "intensity of tension;" then if each small element of the surface of a body be given its proper sign and multiplied by the intensity of force through that small element, this force being also given its proper sign, and if all such products for the whole surface be summed up, the total will be the acceleration of momentum of the body. The direction of this acceleration will be shown by the sign of this total, the sign having reference to the relative position of the surfaces which have been arbitrarily called positive and negative. Thus let two tensions, *i.e.*, positive forces, be applied to two parallel opposite faces, and let the force applied to the positive face be greater than that applied to the negative face; then the body will suffer a positive acceleration of momentum; that is, an acceleration in the direction from the negative face towards the positive face. The faces perpendicular to the positive and negative faces must be given the signs $+\sqrt{-1}$ and $-\sqrt{-1}$.

Thus a pair of positive forces applied to faces with the signs $+1$ and $+\sqrt{-1}$ cannot possibly balance each other. But a positive force applied to a + face can be balanced by a tangential, or shearing, force applied to a $\sqrt{-1}$ face. Because the shearing force has either the sign $+\sqrt{-1}$ or $-\sqrt{-1}$, and multiplied by the sign of the face, gives either $+1$ or -1, as the sign of the product. Surfaces oblique to what is chosen as the positive direction must be considered as partly scalar and partly vector, as also forces oblique to the surfaces through which they act, or rather oblique to their direction of transmission. Oblique surfaces must be multiplied by oblique forces according to the ordinary rule of vector multiplication. This system of notation requires no further explanation, I think, to those who are likely to approve of it.

It has become lately a common habit to look upon those things which are conserved, that is, those which have an enduring existence, as objectively real; while those which may come into existence and go out of it again are considered as objectively unreal. Whether this is a correct philosophic habit or not, it has certainly tended to create suspicion as to the objective reality of all mechanical quantities. A gradually extending recognition of the relativity of these quantities is apt to lead on to a reluctant apprehension that all so-called physical facts are mere formal logical deductions from arbitrary definitions. The dark shadow of distrust first fell upon momentum because the fact that it is distinctly a relative quantity is most easily recognised, and thus became earlier a part and parcel of our familiar ideas. Then somebody suddenly recalled to mind the distinction, according to definition, between external and internal kinetic energy, and found that the external kinetic energy which it had been fondly hoped had some lingering flavour of the ABSOLUTE still clinging to it, was no more than a part of the internal kinetic energy of a larger group of bodies; and it became clear at a glance that energy, that grand ABSOLUTE REALITY which, being once borne into existence by triumphant modern science is now far too carefully conserved by its enthusiastic worshippers to allow of there being any risk of its dropping again out of existence, is just as purely relative in its nature as the velocity which has to be squared in order to calculate its amount. It had been thought that because a velocity has a direction and the square of a velocity has no direction, therefore we might calmly and fearlessly contemplate the total or partial destruction of momentum, steadfast in the assurance that energy would still live for us. And thus with much waiting in fluttering hope and trembling fear upon the brink of the Unseen Universe, and becoming impatient at the non-arrival of any clear intimations of immortality for ourselves, or for energy, or even for matter itself—which is clearly neither more real nor more unreal than her faithful spouse energy—a cloud of dismal despair seemed to be settling on the heads of the scientific nations, when a stern but cheering voice was heard from Munich bidding us be satisfied with our finite human faculty of perceiving relations only, and promising us that, if we would only not aspire to divine knowledge of the absolute, we might KNOW even now and also hereafter.

While admitting fully the relativity of all the physical facts which we may learn, I think it would be very unfortunate if we were to allow ourselves to confuse this with the idea that all mechanics is a mere phantasmagoria conjured up by a process of formal logical deduction from a basis of abitrary definitions. The clearest exponent of this theory of formality in mechanics that has come to my notice is Dr. V. A. Julius, in his letters on "Time" to NATURE, vol. xvi. pp. 122, 420. The argument may be thrown into the form of four short propositions and a conclusion, all of which are derived by purely formal reasoning from the ordinary definitions of the various quantities involved, and which a friend of mine pretends make out a "clear demonstration of the utter absurdity, futility, and falsity of all mechanics."

1. All motions and velocities are simply relative. Within a given isolated system, nothing with reference to the motions of its parts can be known beyond the motions of these parts relatively to the centre of inertia of the system.

2. Relatively to any other system, or single body, the velocity of the centre of inertia of this first system is, by definition, simply the mean of the velocities of its parts. The sum of the velocities of the parts relatively to the centre of inertia of this first system is, therefore, always zero.

3. Within one portion of this system, therefore, there cannot be any loss of average velocity without there being a simultaneous equal gain of average velocity in some other portion.

4. The changes which can possibly take place in the system with regard to velocity consist, therefore, in balanced exchanges of relative momentum between its parts, and, therefore, the equality of "action and reaction"—whether calculated with reference to rate of transference of momentum, or with reference to rate of transference of energy, *i.e.*, rate of doing work—is a purely formal deduction from the definition of the centre of inertia.

Conclusion. A purely formal deduction from an arbitrary definition is just as likely not to agree with reality as to agree with it. Q.E.D.

The fallacy of the argument lies in the artful omission of a few words in 3, which are necessary to make the meaning quite explicit. At the end of 2, the sum set equal to zero is that of the velocities *relatively to the centre of inertia of the system* itself. These, therefore, are the velocities referred to in 3. Therefore, in 4, the exchanges of momentum that are balanced are those of momentum measured relatively to the centre of inertia of the system itself; and it does not at all follow, by *pure logic*, that such a balanced exchange of momentum relatively to this centre does not produce an acceleration of velocity of the centre of inertia relatively to some body outside this system. Of course, if we add this outside body to the first system, then pure logic will compel the exchanges of momentum throughout this new combined system and measured relatively to the centre of inertia of the new combined system to balance. But pure logic does not *necessitate* the exchange of momentum within one part of the system relative to the centre of inertia of that part being unaccompanied by a simultaneous exchange of momentum between that part and some other part, or every other part. Thus the fact of conservation of momentum is not, that when two bodies exchange momentum, the amounts lost and gained measured relatively to the centre of inertia of the two, are numerically equal,—that would be a mere truism—but that the amounts lost and gained measured relatively to a third body are equal to each other. This latter is a physical fact, only to be proved by experiment, not by logic. The statement that action and reaction between two bodies are equal, does not mean anything in particular; but the statement that the action of a force between two bodies does not accelerate the velocity of their centre of inertia relatively to a third body is a statement of experimental fact. The mechanics of a system of two bodies might be built up by means of formal reasoning alone; but not that of a system of three, or of more, bodies without the experimental establishment of the law of conservation of momentum.

And the more complicated the system be, the larger the number of possible combinations of three bodies within it, the greater is the number of experiments or observations we can make to prove that the conservation of momentum is a general physical fact. The larger the number of such observations becomes, the further removed is the doctrine of the conservation of momentum from the character of a logical deduction from definitions.

Still, of course, the doctrine has only to do with relative velocities and relative accelerations of velocities. It loses, however, none of its reality and truthfulness on account of this. Why should not relations be capable of being real, even if not permanent? We are indeed incapable of conceiving anything as real which does not owe its reality in our conception simply to its relations to other things. If objective reality is in any way the opposite of relativity, then, certainly, so far as our knowledge goes, there is no such thing as objective reality. Our notions of momentum and of force, then, are relative to three bodies, and not to two bodies, and this seems to me to be an important point. The ELEMENTARY notion of momentum derived from DEFINITION is relative to TWO bodies only; but the PRACTICAL notion derived from EXPERIENCE is relative to three bodies at least, or to a complicated system of bodies. It should not be forgotten that the physical realities among which we live owe their existence to the complexity of nature. Throughout the complexity there are certain simple invariable relations, and these are the physical laws of nature. The law of conservation of momentum is this: the momentum of one system relative to another system remains unchanged by exchanges of momentum between the parts of the former system. Otherwise stated it is: exchanges of momentum may and do take place between the parts of a system without these exchanges being necessarily accompanied by an exchange of momentum between this system and any other system.

Energy is, of course, a quantity of as relative a character as momentum, although its relativity is not of just the same kind. Energy in general is usually defined as the power of doing work. Curiously enough this definition is frequently followed closely by the statement that a system may possess a very large amount of energy, and yet if there are no differences of potential within it no work can be done by it. The correct statement of what is meant by this last has often been given, viz., that in this case no work can be done by one part of the system upon another part of the same system. But still more often is the inaccuracy indulged in of saying that energy of one kind or another may be transformed into work. Now work is not energy and has no kind of similarity to energy, and therefore energy can never be converted into work. When energy is transferred from one body to another the first does work upon the second, the amount of work done being measured by the amount of energy transferred. The rate at which energy is transferred is the rate of doing work, or the horse-power. The doing of work or more shortly WORK, is the transference of energy from one body to another, but is not the energy itself. The confusion has never entered into the practical use of the word "work," which has always really been applied in the sense here explained, although very probably a good deal of confusion of ideas among both practical and theoretical men, may have been caused by the above noted incorrect statement that energy and work are convertible. The confusion is of the same sort as if we were to use the word force in the sense I have advocated and confuse it with acceleration of momentum. During some transferences of energy there is an invariable transformation of energy. If during the transference, the whole of the energy transferred is also simultaneously transformed, then the rate of doing work is also equal to the rate of transformation, and the amount of work done is numerically equal to the amount of energy transformed. But the phrase "work done" is only used when transference takes place. When a portion of one kind of energy in a body is converted into energy of another kind without any energy leaving the body, it is not the custom to say that work has been done. Work is only done by one body upon another, so that work is the TRANSFERENCE, not the TRANSFORMATION of energy. To say that so much energy has been spent in doing an equivalent amount of work is a convenient and quite allowable mode of saying that this amount of energy has been transferred from the working body without specifying what has become of the energy; that is, without specifying into what other body the energy has been transferred, and without specifying in what form the energy has appeared in the other body. But to say that the energy is converted into work is quite a different thing, and altogether wrong.

When a body possesses in two parts of it two quantities of heat at two different temperatures, the amount of work which the one part has the power of doing on the other in consequence of this difference of temperature is not nearly equal to the whole amount of heat energy in the two parts. Thus the energy in a body is not the power measured quantitatively, possessed by its parts of doing work on each other.

If in a collection of bodies there be a certain one body with a certain amount of kinetic energy, calculated from its velocity, relative to the centre of inertia of the group, that one body might deliver up the whole of this kinetic energy by direct impact upon another body which had zero velocity relative to that centre of inertia, provided these two bodies were exactly alike in certain particulars as to mass and shape. But if there did not exist in the group any body which had this particular relation of shape and velocity to the first, then this first could not possibly deliver up all its kinetic energy, so as to get its velocity relative to the centre of inertia of the whole group reduced to zero. It is thus clear that the internal kinetic energy of a collection of masses is not measured by the amount of kinetic energy calculated from the velocities relative to the centre of inertia of the collection that can be transferred from one part to another.

Also, if another body, or another group of bodies, existed apart from this first group, and possessed a velocity of centre of inertia either zero, or of any other value, relative to the centre of inertia of the first group, the kinetic energy of this first group, measured either relatively to its own centre of inertia, or to that of the other group, or to the centre of inertia of the two combined, could only be wholly transferred to this second group, provided that this second group had very special and very ingeniously contrived relations with regard to mass and configuration to the first group. Thus the kinetic energy of any collection is not measured by the power it may possibly have of doing work upon bodies outside the collection. And quite evidently the same may be said of any other kind of energy possessed by the body.

For each kind of energy we have more or less accurate means of comparing quantitatively different amounts of that kind of energy, and thus of measuring the amount of that kind of energy possessed by a body in terms of the quantity which is adopted as unit of that kind of energy. We have also means of converting different amounts of any one kind into most other kinds of energy; and since in several carefully-made experiments upon the conversion of different kinds of energy there has on the whole been a very fair agreement in the ratios furnished by these experiments between the adopted units of the different kinds, we have come to believe in the truth of the law of conservation of energy—the more especially since this belief is supported by theoretical reasoning based on the hypothesis of the truth of the conservation of momentum. This latter theoretical reasoning, however, we have, hitherto, at any rate succeeded in applying only to transferences of kinetic energy of visible motion, and to the thermodynamics of perfect gases.

But taking this principle of conservation of energy for granted as true, we have the means of measuring the amount of energy of any kind possessed by a body in terms of the adopted unit for kinetic energy of visible motion.

ROBERT H. SMITH

(*To be continued.*)

The Unseen Universe—Paradoxical Philosophy

WILL you permit me to ask through your columns how the idea of the authors—that the present universe is developed out of our unseen universe, which unseen universe is itself developed out of another, and so on in an endless vista up to the unconditioned—works when applied to the present universe as itself developing a lower universe?

The present universe must be a conditioning as well as a conditioned universe, or there would be a breach of the principle of continuity, and there must, on the same principle, be an endless vista of such lower universes.

Have we any hint of any lower universe? Ought we not to have more than a hint? Ought we not to be fully conscious that our own universe is developing and sustaining such a lower universe, to the living intelligent beings in which we are, in fact, supernatural agents, as the angels in the universe above us are to ourselves?

I think that the authors have expanded their idea in one direction only, and I have not seen any reviews of their books applying this idea in the other direction. If, however, this application has been made, I shall be glad to be referred to the passages containing it. W. A. T. HALLOWES

New University Club, St. James's Street, S.W. January 4

Atmospheric Electricity

THE traces afforded by the self-registering electrometer at this observatory show that the conditions of the atmospheric electricity at Kew were very similar during the recent frosts to those observed at Montsouris by M. Descroix. We have, however, in the automatic instrument the great advantage of continuous registration, and therefore our information is not limited to the results afforded by seven observations daily.

The whole period of the frost was characterised by extremely high tension which with us averaged and frequently exceeded the amount which sufficed to derange the French instrument.

The absolute maximum tension recorded equalled 600 volts, and occurred about 4 P.M. on December 16.

The most noticeable feature in the curves of electrical disturbance during the period is that of the daily range of the instrument having attained a maximum usually between 8 to 10 P.M., the tension reaching over 400 volts at the time on the 17th, 18th, and 21st, and over 500 on the 22nd ult.

The fall in tension on the 25th was irregular and the value became almost zero at 6 A.M. on the 26th, for the whole of which day it continued low. Negative electricity was recorded for the first time from 1 to 3 A.M. on the 29th.

Undoubtedly the value of the tension of the atmospheric electricity, as measured by the Thomson electrometer is, as M. Descroix states, only a relative one. We have determined experimentally that with the same instrument the indicated tension is largely influenced by the distance of the nozzle of the water-dropping collector from the wall of the building in which the instrument is placed, and in accordance with a suggestion of Sir W. Thomson, we replace during the passage of thunderstorms our ordinary discharge-tube by a very short one, so as to get the scale of tensions within the range of the electrometer.

Kew Observatory, January 6 G. M. WHIPPLE

Electrical Phenomenon

I HAVE just read in NATURE (vol. xix. p. 182) an account of a strange electrical phenomenon observed at Teignmouth. In connection with it the following incident may be of some interest:—When in Switzerland, not long since, I made with some friends the ascent of Monte Rosa. The weather was unsettled, and on gaining the summit we saw a thunderstorm advancing in our direction from the Italian valleys, and not wishing to turn ourselves into lightning-conductors we deemed it wise to retire from the summit. We had retreated a very short distance along the *arête* when the storm-clouds swept up upon us; the fine snow fell so thick that we could hardly see one another, and we were all suddenly attracted by a peculiar ticking or fizzing from our hair; when I held up my axe the ticking was most distinctly heard from the top of it. The thunder ceased, and we felt that we were acting as points, through which the ground electricity was flowing off into the cloud; if it had been dark, the bluish light observed at Teignmouth might have been visible.

As at Teignmouth, so on Monte Rosa; it was freezing hard when the phenomenon was observed. W. S. GREEN

Alta Terrace, Monkstown, Cork

Time and Longitude

As the questions I propounded under this head in NATURE, vol. xviii. p. 40, have been again alluded to by Mr. E. L. Layard, I may remark that they receive a complete answer in the "Geographical Reader," by C. B. Clarke, M.A. (Macmillan and Co., 1876). At p. 19 he says: "At the town of Sitka, in Alaska, half the population are Russians who have arrived from Russia across Asia; half the population are Americans who have arrived *viâ* the United States. Hence, when it is Sunday with the Russians it is Saturday with the Americans; the Russians are busy on Monday while the Americans are in church on Sunday to the great interruption of business."

It is evident, then, that our new year first commenced in Alaska at 9 A.M. Greenwich time on December 31. Each of our days commences at the same hour and lasts forty-eight hours; the year exists for 366 days. LATIMER CLARK

January 4

Magnetic Storm of May 14, 15

THE magnetic storm of May 14, 15, which was observed simultaneously in England, China, and Australia, and which made itself felt in the telegraph wires of Persia and India, was also perfectly observed in America. Mr. G. F. Kingston, director of the government observatory at Toronto, Canada, has kindly forwarded to me a tracing of his magnetograms, and I find that all the principal inflexions of the declination, as well as of the components of the intensity, bear a striking resemblance to those recorded at the Stonyhurst observatory. The correspondence between the two vertical force curves on May 14 is very remarkable for such distant stations. Comparing the times of the principal minimas in the V.F. trace, and of the chief maximum of the declination, we have the following results in Toronto mean time:—

	Principal V.F. min. P.M.		Secondary V.F. min. P.M.		Decl. Max. P.M.
Toronto Observatory ...	6 17	...	4 0	...	6 39
Stonyhurst Observatory	6 42	...	4 20	...	6 54
	0 25	...	0 20	...	0 15

The disturbing force would thus appear to have been felt somewhat earlier in Canada than in Europe.

The extent of the extreme oscillation of the V.F. magnets cannot be compared, as that at Stonyhurst was too sensitive, and was consequently thrown off its balance; but the rapid movement of the declination needle immediately preceding the maximum was almost identical in England and in Canada, the Stonyhurst curves showing a rise of 28′ 39″ in less than twenty minutes, and that of Toronto an increase of 26′ 53″ in the same time.

It is important to note that I have used the terms maximum and minimum in reference to increase and decrease of ordinate, but it so happens that an increase of ordinate signifies a decrease of H.F. and V.F., and also of W. declination in the Toronto curves, whilst it shows an increase of all these elements in the magnetograms of Stonyhurst. S. J. PERRY

Stonyhurst Observatory, December 28, 1878

Blowpipe Experiment

I BEG to inform you of the following curious results which may be considered of sufficient interest to lead to further investigation of the subject.

Having received a quantity of blowpipe charcoal from Freiberg, about two months ago, I placed two sticks in a "stoneware" jar full of pure water in order to saturate them therewith, so that small squares cut with a saw and placed on aluminium plate as a support, might stand the blowpipe heat longer. I also found that thus treated there is little or no black sawdust, which dirties the hands, &c., more than anything else in blowpipe operations.

Having also placed in the same jar of water two "aluminium spoons" (thick rods about five inches long), I was surprised to find that after the charcoal had sunk to the bottom on saturation, the aluminium rods were covered with semi-opaque roundish *crystals* (part being perfectly transparent) near the surface of the water, and also at the very bottom where the spoons rested on the jar.

Thinking the crystals might be due (although I could not tell how with such a deliquescent substance) to some phosphoric acid I had previously fused upon the aluminium spoons, I cleaned them thoroughly and placed them in fresh pure water with the charcoal about a fortnight ago, and they are again covered with the same kind of crystals. I now carefully scraped the crystals off the aluminium rods with a penknife and placed them on an agate slab, where, when dry, they had a perfectly white, sugary appearance, with some minute transparent fragments. Taking up some of these opaque white fragments upon a hot bead of boric acid, I submitted them to the action of the blowpipe, and found—

(*a*) That they at first emitted a slight yellow pyrochrome, so that they could not be due to *potash*.

(*b*) The green pyrochrome of the boric acid was unaltered (no *soda*).

(*c*) The substance floated in the bead in bluish-white, fat-like, amorphous fragments like alumina or opaque silica as *tabasheer*, but—

(*d*) On continued heating, the fragments gradually disappeared, leaving bubbles, until in half an hour, with fresh boric acid, there was simply a transparent bead left; exactly the behaviour of minute fragments of diamond in boric acid.

Silica is absolutely, and alumina nearly, insoluble in boric acid before the blowpipe.

One conclusion, therefore, seems this: that a slow solution of charcoal in the water takes place, and that crystals of carbon are deposited upon the aluminium.

London, December, 1878 W. A. Ross

Observations on the Microphone

WITH regard to an explanation of the action of the microphone I observed a fact which, though it was already known from some anterior experiments with strong galvanic currents, has not been remarked, as far as I know, with this instrument. On connecting the current from six Grove cells with the microphone (the telephone not being in the circuit) composed of the three carbon rods, the vertical one assumes a vibratory motion between its supports, which causes a very audible sound, especially when placed on a sounding-board.

I think this experiment may serve as another illustration of the well-known fact, discovered by Ampère, of the repulsive action between the subsequent parts of a rectilinear current. Most of the experimental proofs bearing on this point leave some doubt as to a true demonstration, because a dilatation from the heating effect of the very strong currents used with metallic bodies may interfere, and are considered, for example, to explain the experiments of Forbes and Gore.[1] But in my case, with a substance which has a very small coefficient of dilatation, I think the vibratory motion may be considered as an electrodynamic effect. As a supporting demonstration, I suspended with insulated metallic wires near another, three horizontal pieces of carbon (3 cm. long) in such a way that they could move freely away, and the two outer ones were connected with a battery of twenty Grove cells; *immediately* on closing the circuit a repulsion ensued between them and an oscillating motion set in, whilst bright sparks appeared between the contacts.

This experiment may throw some light on a recent controversy which has arisen between Mr. Varley and Prof. Hughes.[2] The latter insists on a change in contact resulting from alternating varying forms of the molecules or their spheres of action, in accordance with the sonorous vibrations. Mr. Varley points out a quite distinct cause. By using a contact-breaker moved with the hand he discovered, on applying a microscope with a 350 times magnifying power when the circuit was closed or opened, a grey cloud issuing between the nearest carbon-points. This seems to prove that little particles of carbon are loosened by an effect of trituration on the contact-surface, the cohesion being lessened by the heating effect of the current. This cloud of microscopic dust serves as a vehicle to the current (when the carbon piece is vibrating), and its resistance of course is easily modified by the impinging sound-vibrations. Now my experiment, though with a strong current, supports this fact, and shows that the vertical carbon is actually vibrating under its influence, and may prepare the above-mentioned condition, or at least render it very ready to change its contact in accordance with sound-waves acting on it with more or less force.

Perhaps it will be observed that a microphone acts very well in transmitting sound when even the weak current from a couple of Leclanché cells is used, but then, also, we may admit a propensity (through the influence of this current) of the vertical carbon rod to get into a vibratory condition, which the sonorous vibrations will easily actuate according to their own period, if really it is not already vibrating at microscopical distances.

Prof. Hughes alludes to au experiment which, as he thinks, gives an evident support to his theory. In a sealed glass tube are inclosed five loose pieces of carbon with terminals to admit a current. He remarks that, properly pressed mere mechanical shaking produces no variation of the current except that due to a constantly increasing resistance caused by abrasion of the carbon contacts, whilst under the influence of sonorous vibrations a varying current is produced, because the tube in this case is varying its length, and the molecules undergo proportional change of form. I think this proof may be as well, and with more probability explained by the facts mentioned above. The tube contains four or five *loose* pieces of carbon, and besides these some air, which, as it is in a closed space, will press from all sides on the carbon parcels when it is put in vibration by sound, and therefore alter in a mechanical way their distances, the more because the surfaces in contact are rough ones. In conclusion I will observe that the audible vibration of the vertical carbon rod in the microphone certainly elucidates the facts discovered by Blyth concerning sound transmitted only with coal cinders forming a receiving and a transmitting apparatus in a galvanic circuit, and on which he insists in a recent communication to this journal (NATURE, vol. xix. p. 72). Shakespeare's Colour-Names

IN the name of scientific accuracy and fair criticism I protest against Mr. Murphy's letter in NATURE, vol. xix. p. 197. His remarks proceed on the perfectly gratuitous assumption that *all* eagles have blue eyes. As this is not a fact (the only live ones I have examined had both of them green eyes), I have no hesitation in asserting that when Shakespeare wrote "An eagle, madam, hath not so green, so quick, so fine an eye as Paris hath," he did so, after having seen an eagle or eagles, and that when he said green he "evidently" meant green, and not blue.

Edinburgh, January 4 A. CRAIG-CHRISTIE

YOUR correspondent, Mr. J. J. Murphy, in his letter, NATURE, vol. xix. p. 197, overlooks the fact that *blue* is quite as inappropriate as *green* to describe the eye of an eagle. Shakespeare would never have used either epithet; the word he made use of was doubtless *keen*. Green has been substituted by the mistake of some transcriber of the play working by ear, and not by eye. I only wonder the correction has not been made long ago by some commentator. ROBERT BREWIN

Exeter, January 4

The Meteor Shower of January 2

AFTER a very heavy fall of rain, sleet, and then snow (equalling in the aggregate 1·472 inch), on the evening and night of January 1, the clouds partly cleared away on the ensuing morning, and during a watch of twenty minutes (6·14 to 6·34 A.M., January 2) in a sky fully two-thirds overcast, fourteen meteors were seen, all of them belonging to the special shower in Quadrans. This radiant was evidently very active at the time I saw it, and in a cloudless sky, must have supplied meteors at the rate of more than one per minute (for one observer). The paths were short and quick without streaks or trains. Radiant point at 230° + 51°, but not very exactly found owing to the clouds and haze through which several of the meteors were indistinctly seen. Three or four were as bright as 1st mag. stars. W. F. DENNING

Ashleydown, Bristol, January 2

OUR ASTRONOMICAL COLUMN

MISSING NEBULÆ.—In Mr. Ellery's Report, to which reference was made last week, it is stated that "two nebulæ, H 4223 and H 1561, widely separated from each other, and described by Herschel as prominent objects, cannot now be found, although careful search has been made for them." The first of these nebulæ is near the cluster Dunlop 413: in the "General Catalogue" it is called "a remarkable object," but being very large and faint, it might, perhaps, be suspected that its invisibility in the Melbourne reflector is owing to the same cause that has led to the Pleiades-nebula, and other similar diffused objects (as G. C. 132, 4570, 5051) being overlooked in very large telescopes though obvious in much smaller ones. But in the case of H 1561 no such supposition is admissible. It was observed by Sir John Herschel on five occasions, in sweeps made between December, 1834, and February, 1836; when best seen it was termed pretty bright, from 25″ to 35″ in diameter, gradually brighter towards the centre, and situate to the south of, though very near to, three stars of the eleventh

magnitude. Taking a mean of the five observations of position, and reducing to 1880, its R.A. is 7h. 35m. 8·0s. and N.P.D., 159° 0′ 46″.

We do not hear of recent observation of the nebula situated near ζ Tauri, which was discovered by Chacornac, and which was sufficiently bright from 1855, October 19, to 1856, January 27, to "cause surprise that it had not been inserted by Mr. Hind upon his ecliptic charts," though it was not perceived on the meridian even with a refractor of 25 centimetres from 1853, December 3, to 1854, December 17. In 1855–56 the nebula was projected upon a star of the eleventh magnitude, the position of which for 1880 is in R.A. 5h. 30m. 16·0s. and N.P.D. 68° 51′ 29″. Chacornac says: "Elle offrait une forme presque rectangulaire, dont le plus grand côte soutendait un angle de trois minutes et demie, et le plus petit un arc de deux minutes et demie." D'Arrest, 1863, September 82, could not perceive any nebulosity about the star, nor, 1165, January 25, "cœlo valde eximio." He notes that the star is double, estimated distance 40″. It precedes ζ Tauri 12·5s., and is north of it 4′ 28″.

Some years since the approximate places of three nebulosities remarked with the comet-seeker at Cambridge, U.S., by Mr. G. P. Bond, but subsequently missed, were published. One seen 1850, February 27, in R.A. 0h. 47m. 41s. ± 1m., N.P.D. 26° 36′ ± 19′, could not be found 1863, September 9. A faint and rather large nebula, seen 1850, December 30, was not to be found, 1863, August 17; R.A. 14h. 37m. ± 3m., N.P.D. 67° 0′ ± 30′, and a third nebulosity resembling a comet, observed 1850, November 7, in R.A. 23h. 50m. 46s., N.P.D. 123° 24′, requires verification; the place is for 1850.

GEOGRAPHICAL NOTES

UNDER the direction of the United States Hydrographic Office, Lieut.-Commander F. M. Green, U.S.N., and the officers under his command, have during the last four years been engaged in determining exactly secondary meridians of longitude by means of the submarine telegraph cables in the West Indies and South America. The result of the West India work in 1874, 1875, and 1876 was the determining the latitude and longitude of a large number of points in the West Indies with the utmost possible exactness; and during the past year this work, of the greatest value to geographical and geodetical science, has been continued by making a chain of telegraphic measurements from the Royal Observatory at Lisbon, by way of Madeira, St. Vincent, Pernambuco, Bahia, Rio de Janeiro, and Monte-Video to Buenos Ayres, there connecting with the observatories of Cordova and Santiago. This chain is perfect, with the exception of one link on the coast of Brazil, where the cable was broken, necessitating the procuring of new cable from England; but its completion will be effected before the computation of the observations already made can be finished. The method used for determining the latitude was in all cases that of the zenith telescope, brought to great perfection by the United States Engineers and the Coast Survey; that for differences of longitude, the comparison by repeated telegraphic signals of two chronometers at the ends of the telegraph cable, determining their errors both before and after the comparison by numerous transits of stars over the meridian. All that is needed to make the work of the last year perfect and complete is the telegraphic determination of the differences of longitude between the Greenwich and Lisbon observatories, and the completion of the imperfect link on the Brazilian coast, both of which will be done during the coming year. Until the observations have been carefully discussed, the results as compared with former determinations cannot be known exactly, but a preliminary computation indicates that the longitude of the coast of Brazil is laid down about three or three and a half miles too far west, this westerly error being indicated in a less degree in the longitudes of Madeira and St. Vincent.

LORD AUGUSTUS LOFTUS has recently forwarded to the Foreign Office, from St. Petersburg, a translation of a Russian letter from Cabul, descriptive of the journey of General Stoletoff's mission from Samarcand, which supplies some notes of interest respecting the country traversed. The road selected for reaching the Oxus was through Huzar, Shirabad, and Chushkogosar, which was traversed in five days. On this route the mission passed through the famous defile known in ancient times under the name of the "Iron Gates," and now called Burghasse Khana. The mission crossed the Oxus in very primitive boats, and marching by night, passed over a sandy arid steppe, and next morning reached Kurshiak settlement, situated in a cultivated country. They made three stages before reaching Mizar and Sheriff, where great crowds thronged the streets, and gazed with curiosity on the people from the distant north. After leaving Tashurgan, the party reached the spurs of the Hindu Kush, and journeyed to Cabul during twenty days. Ascending at first in gentle slopes, the Hindu Kush gradually rises higher and higher, forming, amidst its frequent passes, terraces of increasing height. After traversing a series of such terraces, the mission reached the elevated Bamian Valley (8,500 feet), near which are the Kalu and Great Tran Passes (13,000 feet). Passing the famous Bamian idols, chiselled on the face of the rock, they emerged from the last-named pass, and then descended from the Ugly Pass into the Cabul Darya Valley, at a place three days' journey from the capital of Afghanistan.

THE French papers published last week news from the Gaboon settlements stating that the Ogowe exploring mission had arrived in Libreville, the head city of the colony. A telegram read at the last sitting of the Paris Geographical Society announced that M. Brazza, the chief of the mission, had arrived in Lisbon with some of his subordinates, on his way to Paris. It was expected he would arrive in time for the meeting of the Society on Tuesday. The exploration of the mission has lasted three years, and many highly important results are said to have been obtained.

AT the last sitting of the Paris Geographical Society M. de Lesseps read a telegram received from Capt. Roudaire, stating that he had found nothing but compressed sand when boring to a depth of 30 metres in the Gabes Isthmus, so that no real difficulty prevented the opening of it for the intended Saharan Sea.

ON the authority of Mr. Oscar Dickson, it is stated that the Nordenskjöld expedition is wintering forty miles north of Cape East in Behring Straits. This news has been given to American whalers by a party of trustworthy natives, and a number of whalers are said to be wintering with the *Vega*.

THE just issued October *Bulletin* of the Paris Geographical Society contains a long paper by M. Léon Rousset, giving the results of a journey in the upper basin of the Yellow River and the region of the loess which overspreads so large an area of China, and of which Richthofen makes so much in his great work on China. M. Dutreuil de Rhins contributes a very useful account of Annam and the province of Hué; M. H. Harrisse discusses the question of the burial-place of Columbus, and M. d'Abbadie concludes his useful description of the instruments to be used in travel.

A LITTLE work on Afghanistan has just been published by Dr. Josef Chavanne, the author of the excellent work on the Sahara. It is written with special reference to the

present war, and gives a detailed description of the country and its geographical character, as well as of its inhabitants, from an ethnographical as well as a social point of view. The natural resources and military power of Afghanistan are described, and particular attention has been paid to an account of the communication between India and Afghanistan, the lines of operation, and the numerous mountain passes. There are several illustrations and an excellent map. It is published by Hartleben, of Vienna.

IN a recent voyage from Melbourne to the Fiji Islands, the steamer *Ariel* called at Lord Howe Island, where twenty-five people in all were found. The island is mountainous, of volcanic origin, but well-wooded, about five miles long, and from one and a half to two miles broad, and is situated some 400 miles east of Sydney. The communication of the inhabitants with the outer world is nowadays very uncertain, as whalers but rarely visit them.

THE MUSICAL ASSOCIATION[1]

THE question, In what way does science enter into the subject of music? is one that by no means admits of an easy answer. If we were to put it to various persons interested in music in different ways we should find their opinions most vague and contradictory. A university scholar, or a physical lecturer, would make the science of music consist entirely in the doctrines of acoustics; while, on the other hand, we should find some of the most eminent musical professors telling us that these had nothing to do with music at all, but that science meant the study and application of the rules of musical composition. Or possibly it might even be held that a skilful manipulation of the violin, or an appropriate management of the voice in singing, or an intelligent phrasing of pianoforte passages, or other refinements of execution, constituted all the science that musicians need aspire to.

A quarter of a century ago such a question would have excited no interest. People in general were satisfied to take the art as they practically found it, and troubled themselves but little as to the principles on which it was based. But the march of knowledge has changed the aspect of the matter. Modern philosophical investigation has included music in the universality of its aims, and the musician, however conservative, must submit to a searching inquiry as to the real nature of the stuff in which he deals.

The great work of Helmholtz, published in 1863, gave the first real stimulus to scientific musical inquiry; and although many years passed before it became much known in this country it at length aroused attention, and some of the most intelligent students of the art began to see that there was really something to be inquired into—the first step towards accurate knowledge of any kind. They observed the beneficial operation of the learned societies, where papers on the subjects they embraced were brought forward; and the idea occurred to them that an association of a similar character for music would not only enable the scientific questions connected with it to be publicly discussed, but might also be made conducive to the welfare of the art in a practical point of view. The idea was mentioned to one of the most eminent men of science (now president of the Royal Society), who, warmly approving it, issued the following circular:—

"50, *Grosvenor Place, April* 8, 1874

"DEAR SIR,—It has been suggested by several leading persons interested both in the theory and practice of music, that the formation of a society similar in the main features of its organisation to existing learned societies would be a great public benefit. Such a musical society might comprise among its members the foremost musicians, theoretical as well as practical, of the day, the principal patrons of art, and also those scientific men whose researches have been directed to the science of acoustics and to kindred inquiries. Its periodical meetings might be devoted partly to the reading of papers upon the history, the principles, and the criticism of music, partly to the illustration of such papers by actual performance, and partly to the exhibition and discussion of experiments relating to theory and construction of musical instruments, or to the principles and combinations of musical sounds.

"With a view to ascertain the opinions of persons interested in these subjects, and to attempt a more precise definition of the objects and constitution of such a society, it is proposed to hold a meeting here, at which your presence is requested on Thursday, April 16, at 2.30 P.M.

"I am, dear sir, yours faithfully,

"(Signed) W. SPOTTISWOODE"

This led to the formation of the Association whose proceedings are mentioned at the head of this article. The rules were judiciously framed, so as to avoid the rocks on which former musical societies had been shipwrecked; and the society has now gone successfully through four sessions. We learn from the report just issued, at the commencement of the fifth year, that the finances are prosperous, that the meetings are well attended, that the officers are zealous and efficient, and that a series of good papers are forthcoming for the future; from all which it may be fairly inferred that the institution has taken a permanent position.

The character of the society is, of course, best displayed by the contents of its *Transactions*. We cannot pretend to review the thirty-six papers (some of them very elaborate) contained in the four volumes before us; it will be an easier course to indicate briefly, in the first instance, what are the "subjects connected with the art and science of music" which more especially deserve "investigation and discussion," and then to see how far the papers actually presented to the Association have fulfilled the object aimed at in its title.

Giving precedence to science, one may conceive that the "Principles and Phenomena of Acoustics" would claim attention. It is true, as has already been hinted, that some eminent practical musicians repudiate the relevancy of these inquiries, and discourage their study, on the ground that a knowledge of acoustics is unnecessary to the practical musician, whether composer or performer.[2]

But fortunately the general spread of education sufficiently disposes of arguments of this kind. There are, and no doubt always will be, persons who are satisfied with the minimum amount of knowledge to enable them to earn their daily bread, but it is to be hoped the number is decreasing every day. A man who lives by an art will, if his mind be properly constituted, be in no wise reluctant to learn all he can about it, even though the knowledge may not be immediately convertible into money. Musicians must, in spite of the disparaging opinion of some of their leaders, be treated as intelligent beings, who have minds capable of enlightenment and instruction, and surely there is nothing unreasonable in assuming that the philosophical principles on which their art depends must present some interest to them, if laid before them in an intelligible form. The doctrine that such knowledge should be confined to cultivated amateurs, and forbidden to professional musicians, is simply a libel on the intelligence of those to whom we owe enjoyment of so high an order. If, then, these principles are to be studied, the science of acoustics must necessarily form the basis of the study. The splendid

[1] Proceedings of the Musical Association for the Investigation and Discussion of Subjects connected with the Art and Science of Music. Vols. i. to iv. First Session, 1874-5; Second Session, 1875-6; Third Session, 1876-7; Fourth Session, 1877-8.

[2] It is a remarkable example of this view that in a new elaborate and voluminous English "Dictionary of Music," now in course of publication, the word *Acoustics* finds no place.

investigations of Helmholtz as to the nature of musical sounds and musical sensations form a fund of knowledge of the most interesting and instructive kind, and illustration and discussion of such topics would be by no means out of place before the society. We believe that the great fundamental fact of the compound nature of musical sounds, which now has become as firmly established as any physical fact can be, is hardly yet understood, or its great significance appreciated by the great mass of the persons who have to do with its effects every day of their lives.

It happens, however (no doubt for good and sufficient reasons), that the more abstract principles of acoustics have received but little attention in the society. We only notice three papers which come within this category, and these on quite subsidiary points, namely, "On our Perception of the Direction of a Source of Sound," by Lord Rayleigh; "On the Sensitiveness of the Ear to Pitch and Change of Pitch," by Mr. A. J. Ellis; and "On the Musical Inventions and Discoveries of the late Sir C. Wheatstone," by Prof. W. G. Adams.

But the science of acoustics is a very different thing from the theory of music. There is much misunderstanding on this point; many people confuse the two, whereas the former is in reality only the introduction to the latter. A student may be well acquainted with all the scientific facts and theories relating to the production and transmission of musical sounds, and yet know nothing of the mode in which these data bear on music itself. Helmholtz, who, with wonderful knowledge and sagacity, appears to have anticipated almost every possible view of the subject, has fully expressed this distinction not only in the substance of his great work, but in its very title-page. He calls it "Die Lehre von den Tonempfindungen *als physiologische Grundlage* für die Theorie der Musik," thereby declaring that the acoustical doctrines he so admirably lays down are not to be considered as forming of themselves a theory of music, but are merely intended to *serve as a basis* for such a theory. Starting from these data, it becomes necessary to consider the influence they have on the varied and complicated forms and rules which guide the structure of musical composition, as, for example, the construction of the ordinary scale, the nature of chromatic notes, tonality, the combinations and progressions of harmony, the rules of melodial counterpoint, musical form, and so on. A crowd of most interesting questions arise as to how far all these practical matters have been influenced by the physical properties of musical sounds, or how far they are the result of free artistic invention. Helmholtz devotes the second part of his work to the discussion of these and kindred questions, on which, aided by a competent knowledge of music, his great reasoning powers have enabled him to throw much new light. But this part of his labours has been hitherto almost a sealed book to musicians; it is difficult, often elaborate, and sometimes obscure, and the interpreters who have so ably popularised his acoustical researches have stopped short before venturing on what was to physicists a less familiar region. Yet this is by far the most important section of the work, from a musical point of view; it is, in fact, the real "Theory of Music," the true musical philosophy, in which the proper application of science to music is to be found; moreover, unlike abstract acoustics, it touches closely on the practice of the musical art, and the habits of thought of its professors. There are few teachers of musical composition who do not to some extent attempt to found their instruction on natural principles, or what they think to be such; but the theories thus propounded are for the most part crude, vague, and founded on merely empirical fancies, having no philosophical origin, and such as will not stand the test of scientific investigation or strict logical reasoning; and hence we can hardly wonder at the fact that they rather obstruct than aid the efficiency of musical instruction.

This subject, therefore, the "Application of Scientific Data and Scientific Reasoning to the Theory of Music," is one which offers every inducement for the higher order of musical study, and its discussion is eminently in place in such a society as that before us. The results of the modern investigations are so new, and in many respects so antagonistic to the ideas hitherto prevailing among musicians, that it is not to be expected they will be at once fully understood or favourably received. Already a considerable amount of opposition has been manifested to them; it is reasonable and proper that they should be fairly considered, and it is in the highest degree desirable that they should be clearly explained. The subject has not been neglected at the meetings of the Association, for, although no systematic treatment of it has yet been attempted, we find no less than eight papers on various points of theoretical detail. Four of these are on intonation and temperament (a favourite theme with musical mathematicians, but somewhat unpalatable to practical men, who consider the out-of-tune equal division of the octave "good enough for them"); a fifth aims at exposing the fallacies and inconsistencies of certain of the old theoretical systems; another treats of the philosophical nature of intervals and of the construction of the scale; another expounds some elementary views on harmony; and the eighth exhibits various numerical calculations on musical ratios, &c.

Another point that furnishes a most profitable topic of study is *musical history*. It is impossible to look far into music without becoming aware how largely modern form and structure are derived from what has gone before, and the careful examination of this clears up many points of theory for which no other sufficient explanation can be found. Nothing could be more in place for a "musical association" than historical papers, not as mere matters of antiquarian curiosity, but as bearing on the various changes of musical form. We only, however, find two historical papers, one, an instructive essay, by Sir Frederick Ouseley, on the "History of Ecclesiastical Music in Western Europe," the other an interesting monograph, by Mr. Cummings, on "Purcell."

The *construction of musical instruments* offers a large and varied source of interest, combining the laws of acoustics, the application of mechanical skill and invention, and the adaptation to practical musical use. There are six papers on this, relating to stringed and brass instruments, drums, and the voice.

Finally, there are abundance of topics connected with *the practice of the musical art* which admit of discussion in such a society; for although, in a scientific journal, it is our chief province to point to the subjects in which science takes part, yet it would be a misuse of the society to let these predominate to the prejudice of the more practical matters which come home more directly to professional men, and we consider it a good evidence of the flourishing condition and prospects of the society that these practical points have received so large a share of attention. By far the larger number of the papers have been of this practical kind, relating to musical notations and nomenclature, criticism, practical standards of pitch, the analysis of great musical works, pianoforte playing, the cultivation of sacred music, the connection of music with language, the laws of expression, modes of tuition, and musical libraries. A paper on the last-named subject led to a memorial to the British Museum, and elicited an answer explaining the facilities which that institution affords for musical reference and study.

The Association deserves the support and co-operation of every one interested in the cultivation of music either theoretically or practically, and we cordially wish it the permanent success it seems in a fair way to attain.

W. POLE

DISCUSSION OF THE WORKING HYPOTHESIS THAT THE SO-CALLED ELEMENTS ARE COMPOUND BODIES[1]

II.

Application of the above Views to Calcium, Iron, Lithium, and Hydrogen

Calcium

IT was in a communication to the Royal Society made now some time ago (*Proc.*, vol. xxii. p. 380, 1874), that I first referred to the possibility that the well-known line-spectra of the elementary bodies might not result from the vibration of similar molecules. I was led to make the remark in consequence of the differences to which I have already drawn attention in the spectra of certain elements as observed in the spectrum of the sun and in those obtained with the ordinary instrumental appliances.

Later (*Proc.* Roy. Soc., No. 168, 1876) I produced evidence that the molecular grouping of calcium which, with a small induction-coil and small jar, gives a spectrum with its chief line in the blue, is nearly broken up in the sun, and quite broken up in the discharge from a large coil and jar, into another or others with lines in the violet.

I said "another," or "others," because I was not then able to determine whether the last-named lines proceeded from the same or different molecules; and I added that it was possible we might have to wait for photographs of the spectra of the brighter stars before this point could be determined.

I also remarked that this result enabled us to fix with very considerable accuracy the electric dissociating conditions which are equivalent to that degree of dissociation at present at work in the sun.

In Fig. 3 I have collected several spectra copied from photographs in order that the line of argument may be grasped.

First we see what happens to the non-dissociated and the dissociated chloride. Next we have the lines with a weak voltaic arc, the single line to the right (W L

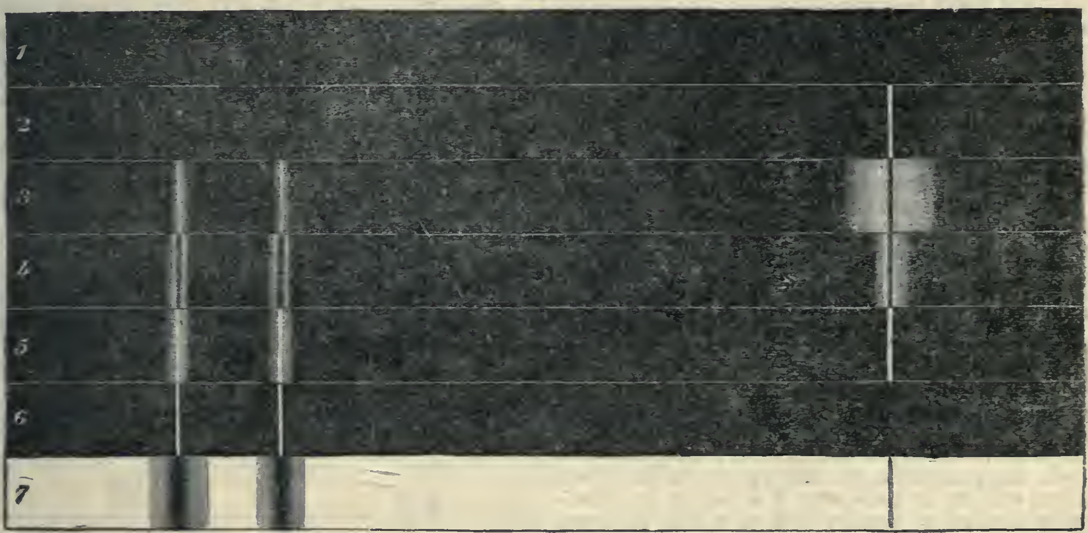

FIG. 3.—The blue end of the spectrum of calcium under different conditions. 1. Calcium is combined with chlorine ($CaCl_2$). When the temperature is low, the compound molecule vibrates as a whole, the spectrum is at the red end, and no lines of calcium are seen. 2. The line of the metal seen when the compound molecule is dissociated to a slight extent with an induced current. 3. The spectrum of metallic calcium in the electric arc with a small number of cells. 4. The same when the number of cells is increased 5. The spectrum when a coil and small jar are employed. 6. The spectrum when a large coil and large jar are used. 7. The absorption of the calcium vapour in the Sun.

4226·3) is much thicker than the two lines (W L 3933 and 3968) to the left, and reverses itself.

We have next calcium exposed to a current of higher tension. It will be seen that here the three lines are almost equally thick, and all reverse themselves.

Now it will be recollected, that in the case of known compounds the band structure of the true compounds is reduced as dissociation works its way, and the spectrum of each constituent element makes its appearance. If in 3 we take the wide line as representing the banded spectrum of the compound, and the thinner ones as representing the longest elemental lines making their appearance as the result of partial dissociation, we have, by hypothesis, an element behaving like a compound.

If the hypothesis be true, we ought to be able not only to obtain, with lower temperatures, a still greater preponderance of the single line, *as we do;* but with higher temperatures, a still greater preponderance of the double ones, *as we do.*

I tested this in the following manner:—Employing photography, because the visibility of the more refrangible lines is small, and because a permanent record of an experiment, free as it must be from all bias, is a very precious thing.

Induced currents of electricity were employed in order that all the photographic results might be comparable.

To represent the lowest temperature I used a small induction coil and a Leyden jar only just large enough to secure the requisite amount of photographic effect. To represent the highest, I used the largest coil and jar at my disposal. The spark was then taken between two aluminium electrodes, the lower one cup-shaped, and charged with a salt of calcium.

In the figure I give exact copies of the results obtained. It will be seen that with the lowest temperature only the single line (2) and with the highest temperature only the two more refrangible lines (6) are recorded on the plate.

This proved that the intensity of the vibrations was quite changed in the two experiments.

Perhaps it may not be superfluous here to state the reasons which induced me to search for further evidence in the stars.

[1] Paper read at the Royal Society, December 12, 1878, by J. Norman Lockyer, F.R.S. Continued from p. 201.

It is abundantly clear that if the so-called elements, or more properly speaking their finest atoms—those that give us line spectra—are really compounds, the compounds must have been formed at a very high temperature. It is easy to imagine that there may be no superior limit to temperature, and therefore no superior limit beyond which such combinations are possible, because the atoms which have the power of combining together at these transcendental stages of heat do not exist as such, or rather they exist combined with other atoms, like or unlike, at all lower temperatures. Hence association will be a combination of more complex molecules as temperature is reduced, and of dissociation, therefore, with increased temperature there may be no end.

That is the first point.

The second is this :—

We are justified in supposing that our "calcium," once formed, is a distinct entity, whether it be an element or not, and therefore, by working at it alone, we should never know whether the temperature produces a single simpler form or more atomic condition of the same thing, or whether we actually break it up into X + Y, because neither X nor Y will ever vary.

But if calcium be a product of a condition of relatively lower temperature, then in the stars, hot enough to enable its constituents to exist uncompounded, we may expect these constituents to vary in quantity; there may be more of X in one star and more of Y in another; and if this be so, then the H and K lines will vary in thickness, and the extremest limit of variation will be that we shall only have H representing, say X in one star, and only have K representing, say Y in another. Intermediately between these extreme conditions we may have cases in which, though both H and K are visible, H is thicker in some and K is thicker in others.

Prof. Stokes was good enough to add largely to the value of my paper as it appeared in the *Proceedings* by appending a note pointing out that "When a solid body such as a platinum wire, traversed by a voltaic current, is heated to incandescence, we know that as the temperature increases not only does the radiation of each particular refrangibility absolutely increase, but the proportion of the radiations of the different refrangibilities is changed, the proportion of the higher to the lower increasing with the temperature. It would be in accordance with analogy to suppose that as a rule the same would take place in an incandescent surface, though in this case the spectrum would be discontinuous instead of continuous. Thus if A, B, C, D, E denote conspicuous bright lines of increasing refrangibility in the spectrum of the vapour, it might very well be that at a comparatively low temperature A should be the brightest and the most persistent; at a higher temperature, while all were brighter than before, the relative brightness might be changed, and C might be the brightest and the most persistent, and at a still higher temperature E."

On these grounds Prof. Stokes, while he regarded the facts I mentioned as evidence of the high temperature of the sun, did not look upon them as *conclusive* evidence of the dissociation of the molecule of calcium.

Since that paper was sent in, however, the appeal to the stars to which I referred in it has been made, and made with the most admirable results, by Dr. Huggins.

The result of that appeal is that the line which, according to Prof. Stokes' view, should have prevailed over all others, as Sirius is acknowledged to be a hotter star than our sun, is that, if it exists at all in the spectrum, it is so faint that it was not recognised by Dr. Huggins in the first instance.

In Sirius, indeed, the H line due to one molecular grouping of calcium is as thick as are the hydrogen lines as mapped by Secchi, while the K line, due to another molecular grouping, which is equally thick in the spectrum of the sun, has not yet made its appearance.

In the sun, where it is as thick as H, the hydrogen lines have vastly thinned.

While this paper has been in preparation, Dr. Huggins has been good enough to communicate to me the results of his most important observations, and I have also had an opportunity of inspecting several of the photographs which he has recently taken. The result of the recent work has been to show that H and *h* are of about the same breadth in Sirius. In α Aquilæ while the relation of H to *h* is not greatly changed, a distinct approach to the solar condition is observed, K being now unmistakably present, although its breadth is small as compared with that of H. I must express my obligations to Dr. Huggins for granting me permission to enrich my paper by reference to these unpublished observations. His letter, which I have permission to quote, is as follows :—

"It may be gratifying to you to learn that in a photograph I have recently taken of the spectrum of α Aquilæ there is a line corresponding to the more refrangible of the solar H lines [that is K], but about half the breadth of the line corresponding to the first H lines.

"In the spectra of α Lyræ and Sirius the second line is absent."

Prof. Young's observations of the chromospheric lines, to which I shall afterwards refer, give important evidence regarding the presence of calcium in the chromosphere of the sun. He finds that the H and K lines of calcium are strongly reversed in every important spot, and that in solar storms H has been observed injected into the chromosphere seventy-five times, and K fifty times, while the blue line at W. L. 4226·3, the all-important line at the arc-temperature, was only injected thrice.

Further, in the eclipse observed in Siam in 1875, the H and K lines left the strongest record in the spectrum of the chromosphere, while the line near G in a photographic region of much greater intensity was not recorded at all. In the American eclipse of the present year the H and K lines of calcium were distinctly visible at the base of the corona, in which for the first time the observers could scarcely trace the existence of any hydrogen.

To sum up, then, the facts regarding calcium, we have first of all the H-line differentiated from the others

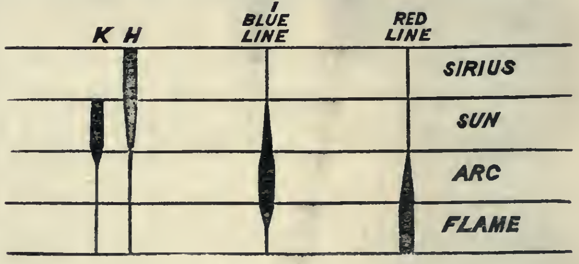

Fig. 4.—The Molecular Groupings of Calcium.

by its almost solitary existence in Sirius. We have the K-line differentiated from the rest by its birth, so to speak, in α Aquilæ, and the thickness of its line in the sun, as compared to that in the arc. We have the blue line differentiated from H and K by its thinness in the solar spectrum while they are thick, and by its thickness in the arc while they are thin. We have it again differentiated from them by its absence in solar storms in which they are almost universally seen, and finally, by its absence during eclipses, while the H and K lines have been the brightest seen or photographed. Last stage of all, we have calcium, distinguished from its salts by the fact that the blue line is only visible when a high temperature is employed, each salt having a definite spectrum of its own, in which none of the lines to which I have drawn attention appear, so long as the temperature is kept below a certain point.

Iron

With regard to the iron spectrum I shall limit my remarks to that portion of it visible on my photographic plates between H and G. It may be described as a very complicated spectrum so far as the number of lines is concerned in comparison with such bodies as sodium and potassium, lead, thallium, and the like, but unlike them again it contains no one line which is clearly and unmistakably reversed on all occasions. Compared, however, with the spectrum of such bodies as cerium and uranium the spectrum is simplicity itself.

Now among these lines are two triplets, two sets of three lines each, giving us beautiful examples of those repetitions of structure in the spectrum which we meet with in the spectra of almost all bodies, some of which have already been pointed out by Mascart, Cornu, and myself. Now the facts indicate that these two triplets are not due to the vibration of the same molecular grouping which gives rise to most of the other lines. They are as follows. In many photographs in which iron has been compared with other bodies, and in others again in which iron has been photographed as existing in different degrees of impurity in other bodies, these triplets have been seen almost alone, and the relative intensity of them, as compared with the few remaining lines, is greatly changed. In this these photographs resemble one I took three years ago, in which a large coil and jar were employed instead of the arc, which necessitated an exposure of an hour instead of two minutes. In this the triplet near G is very marked, the two adjacent lines more refrangible near it, which are seen nearly as strong as the triplet itself in some of the arc photographs I possess, are only very faintly visible, while dimmer still are seen the lines of the triplet between H and *h*.

There is another series of facts in another line of work. In solar storms, as is well known, the iron lines sometimes make their appearance in the chromosphere. Now, if we were dealing here with one molecular grouping, we should expect the lines to make their appearance in the order of their lengths, and we should expect the shortest lines to occur less frequently than the longest ones. Now, precisely the opposite is the fact. One of the most valuable contributions to solar physics that we possess is the memoir in which Prof. C. A. Young records his observation of the chromospheric lines, made on behalf of the United States Government, at Sherman, in the Rocky Mountains. The glorious climate and pure air of this region, to which I can personally testify, enabled him to record phenomena which it is hopeless to expect to see under less favourable conditions. Among these were injections of iron vapour into the chromosphere, the record taking the form of the number of times any one line was seen during the whole period of observation.

Now two very faint and short lines close to the triplet near G were observed to be injected thirty times, while one of the lines of the triplet was only injected twice.

The question next arises, Are the triplets produced by one molecular grouping or by two? This question I also think the facts help us to answer. I will first state by way of reminder that in the spark photograph the more refrangible triplet is barely visible, while the one near G is very strong. Now if one molecular grouping alone were in question this relative intensity would always be preserved however much the absolute intensity of the compound system might vary, but if it is a question of two molecules we might expect that in some of the regions open to our observation we should get evidence of cases in which the relative intensity is reversed or the two intensities are assimilated. What might happen does happen; the relative intensity of the two triplets in the spark photograph is grandly reversed in the spectrum of the sun. The lines barely visible in the spark photograph are among the most prominent in the solar spectrum, while the triplet which is strong in that photograph is represented by Fraunhofer lines not half so thick. Indeed, while the hypothesis that the iron lines in the region I have indicated are produced by the vibration of one molecule does not include all the facts, the hypothesis that the vibrations are produced by at least three distinct molecules includes all the phenomena in a most satisfactory manner.

Lithium

Before the maps of the long and short lines of some of the chemical elements compared with the solar spectra, which were published in the *Phil. Trans.* for 1873, "Plate IX.," were communicated to the Society, I very carefully tested the work of prior observers on the non-coincidence of the red and orange lines of that metal with the Fraunhofer lines, and found that neither of them were strongly if at all represented in the sun, and this remark also applies to a line in the blue at wave-length 4,603.

The photographic lithium line, however, in the violet, has a strong representative among the Fraunhofer lines.

Applying, therefore, the previous method of stating the facts, the presence of this line in the sun differentiates it from all the others. For the differentiation of the red and yellow lines I need only refer to Bunsen's spectral analytical researches, which were translated in the *Phil. Mag.*, December, 1875.

In Plate IV. two spectra of the chloride of lithium are given, one of them showing the red line strong and the yellow one feeble, the other showing merely a trace of the red line, while the intensity of the yellow one is much increased, and a line in the blue is indicated. Another notice of the blue line of lithium occurs in a discourse by Prof. Tyndall, reprinted in the *Chemical News*, and a letter of Dr. Frankland's to Prof. Tyndall, dated November 7, 1861. This letter is so important for my argument, that I reprint it entire from the *Philosophical Magazine*, vol. xxii. p. 472:—

"On throwing the spectrum of lithium on the screen yesterday, I was surprised to see a magnificent blue band. At first I thought the lithic chloride must be adulterated with strontium, but on testing it with Steinheil's apparatus it yielded normal results without any trace of a blue band. I am just now reading the report of your discourse in the *Chemical News*, and I find that you have noticed the same thing. Whence does this blue line arise? Does it really belong to the lithium, or are the carbon points or ignited air guilty of its production? I find there blue bands with common salt, but they have neither the definiteness nor the brilliancy of the lithium band. When lithium wire burns in air it emits a somewhat crimson light; plunge it into oxygen, and the light changes to bluish white. This seems to indicate that a high temperature is necessary to bring out the blue ray."

"POSTSCRIPT, Nov. 22, 1861.—I have just made some further experiments on the lithium spectrum, and they conclusively prove that the appearance of the blue line depends entirely on the temperature. The spectrum of lithic chloride, ignited in a Bunsen's burner flame, does not disclose the faintest trace of the blue line; replace the Bunsen's burner by a jet of hydrogen (the temperature of which is higher than that of the Bunsen's burner) and the blue line appears, faint, it is true, but sharp and quite unmistakable. If oxygen now be slowly turned into the jet, the brilliancy of the blue line increases until the temperature of the flame rises high enough to fuse the platinum, and thus put an end to the experiment."

These observations of Profs. Tyndall and Frankland differentiate this blue line from those which are observed at low temperatures. The line in the violet to which I have already referred, is again differentiated from all the rest by the fact that it is the only line in the spectrum of

the sun which is strongly reversed, so far as our present knowledge extends. The various forms of lithium, therefore, may be shown in the following manner.

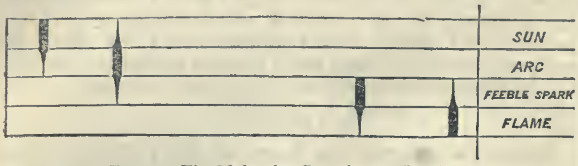

FIG. 5.—The Molecular Groupings of Lithium.

It is remarkable that in the case of this body which at relatively low temperature goes through its changes, its compounds are broken up at the temperature of the Bunsen burner. The spectrum, *e.g.* of the chloride, so far as I know, has never been seen.

Hydrogen

All the phenomena of variability and inversion in the order of intensity presented to us in the case of calcium can be paralleled by reference to the knowledge already acquired regarding the spectrum of hydrogen.

Dr. Frankland and myself were working together on the subject in 1869. In that year (*Proc.*, No. 112) we pointed out that the behaviour of the *h* line was *hors ligne*, and that the whole spectrum could be reduced to one line, F.

"1. The Fraunhofer line on the solar spectrum, named *h* by Angström, which is due to the absorption of hydrogen, is not visible in the tubes we employ with low battery and Leyden-jar power; it may be looked upon, therefore, as an indication of relatively high temperature. As the line in question has been reversed by one of us in the spectrum of the chromosphere, it follows that the chromosphere, when cool enough to absorb, is still of a relatively high temperature.

"2. Under certain conditions of temperature and pressure, the very complicated spectrum of hydrogen is reduced in our instrument *to one line in the green* corresponding to F in the solar spectrum."

As in the case of calcium also, solar observation affords us most precious knowledge. The *h* line was missing from the protuberances in 1875, as will be shown from the accompanying extract from the Report of the Eclipse Expedition of that year:—

"During the first part of the eclipse two strong protuberances close together are noticed; on the limb towards the end these are partially covered, while a series of protuberances came out at the other edge. The strongest of these protuberances are repeated three times, an effect of course of the prism, and we shall have to decide if possible the wave-lengths corresponding to the images. We expect *à priori* to find the hydrogen lines represented. We know three photographic hydrogen lines: F, a line near G, and *h*. F is just at the limit of the photographic part of the spectrum, and we find indeed images of protuberances towards the less refrangible part at the limit of photographic effect. For, as we shall show, a continuous spectrum in the lower parts of the corona has been recorded, and the extent of this continuous spectrum gives us an idea of the part of the spectrum in which each protuberance line is placed. We are justified in assuming, therefore, as a preliminary hypothesis, that the least refrangible line in the protuberance shown on the photograph is due to F, and we shall find support of this view in the other lines. In order to determine the position of the next line the dispersive power of the prism was investigated. The prism was placed on a goniometer table in minimum deviation for F, and the angular distance between F and the hydrogen line near G, *i.e.*, $H\gamma$, was found, as a mean of several measurements, to be 3′. The goniometer was graduated to 15″, and owing to the small dispersive power, and therefore relatively great breadth of the slit, the measurement can only be regarded as a first approximation. Turning now again to our photographs, and calculating the angular distance between the first and second ring of protuberances, we find that distance to be 3′ 15″. We conclude, therefore, that this second ring is due to hydrogen. We, therefore, naturally looked for the third photographic hydrogen line, which is generally called *h*, but we found no protuberance on our photographs corresponding to that wave-length. Although this line is always weaker than $H\gamma$, its absence on the photograph is rather surprising, if it be not due to the fact that the line is one which only comes out at a high temperature. This is rendered likely by the researches of Frankland and Lockyer (*Proc.* Roy. Soc., vol. xvii. p. 453).

"We now turn to the last and strongest series of protuberances shown on our photographs. The distance between this series and the one we have found reason for identifying with $H\gamma$ is very little greater than that between $H\beta$ and $H\gamma$. Assuming the distances equal, we conclude that the squares of the inverse wave-lengths of the three series are in arithmetical progression. This is true as a first approximation. We then calculated the wave-length of this unknown line, and found it to be approximately somewhat smaller than 3,957 tenth-metres. No great reliance can be placed, of course, on the number, but it appears that the line must be close to the end of the visible spectrum.

"In order to decide if possible what this line is due to, we endeavoured to find out both by photography and fluorescence whether hydrogen possesses a line in that part of the spectrum. We have not at present come to any definite conclusion. In vacuum tubes prepared by Geissler containing hydrogen, a strong line more refrangible than H is seen, but these same tubes show between $H\gamma$ and $H\delta$, other lines known not to belong to hydrogen, and the origin of the ultra-violet line is therefore difficult to make out. We have taken the spark in hydrogen at atmospheric pressures, as impurities are easier to eliminate, but a continuous spectrum extends over the violet and part of the ultra-violet, and prevents any observation as to lines. We are going on with experiments to settle this point.

"Should it turn out that the line is not due to hydrogen, the question will arise what substance it is due to. It is a remarkable fact that the calculated wave-length comes very close to H. Young has found that these calcium lines are always reversed in the penumbra and immediate neighbourhood of every important sun-spot, and calcium must therefore go up high into the chromosphere. We draw attention to this coincidence, but our photographs do not allow us to draw any certain conclusions.

"At any rate, it seems made out by our photographs that the photographic light of the protuberances is in great part due to an ultra-violet line which does not certainly belong to hydrogen. The protuberances as photographed by this ultra-violet ray seem to go up higher than the hydrogen protuberances, but this may be due to the relative greater length of the line."

In my remarks upon calcium I have already referred to the fact that the line which our observation led us to believe was due to calcium in 1875, was traced to that element in this year's eclipse. The observations also show the curious connection that, at the time when the hydrogen lines were most brilliant in the corona, the calcium lines were not detected; next, when the hydrogen lines, being still brilliant, the *h* line was not present (a condition of things which, in all probability, indicated a reduction of temperature), calcium began to make itself unmistakably visible; and finally, when the hydrogen lines are absent, H and K become striking objects in the spectrum of the corona.

To come back to *h*, then, I have shown that Dr.

Frankland and myself, in 1869, found that it only made its appearance when a high tension was employed. We have seen that it was absent from among the hydrogen lines during the eclipse of 1875.

I have now to strengthen this evidence by the remark that it is always the shortest line of hydrogen in the chromosphere.

I now pass to another line of evidence.

I submit to the Society a photograph of the spectrum of indium, in which, as already recorded by Thalèn, the strongest line is one of the lines of hydrogen (*h*), the other line of hydrogen (near G) being absent. I have observed the C line in the spark produced by the passage of an induced current between indium poles in dry air.

As I am aware how almost impossible it is to render air perfectly dry, I made the following differential experiment. A glass tube with two platinum poles about half an inch apart was employed. Through this tube a slow current of air was driven after passing through a U-tube one foot high, containing calcic chloride, and then through sulphuric acid in a Wolff's bottle. The spectrum of the spark passing between the platinum electrodes was then observed, a coil with five Grove cells and a medium-sized jar being employed. Careful notes were made of the brilliancy and thickness of the hydrogen lines as compared with those of air. This done, a piece of metallic indium, which was placed loose in the tube, was shaken so that one part of it rested against the base of one of the poles, and one of its ends at a distance of a little less than half an inch from the base of the other pole. The spark then passed between the indium and the platinum. The red and blue lines of hydrogen were then observed both by my friend Mr. G. W. Hemming, Q.C., and myself. Their brilliancy was most markedly increased. This unmistakable indication of the presence of hydrogen, or rather of that form of hydrogen which gives us the *h* line alone *associated into* that form which gives us the blue and red lines, showed us that in the photograph we were not dealing with a physical coincidence, but that in the arc this special form of hydrogen had really been present; that it had come from the indium, and that it had registered itself on the photographic plate, although ordinary hydrogen persistently refuses to do so. Although I was satisfied from former experiments that occluded hydrogen behaves in this respect like ordinary hydrogen, I begged my friend Mr. W. C. Roberts, F.R.S., chemist to the Mint, to charge a piece of palladium with hydrogen for me. This he at once did, and I take this present opportunity to express my obligation to him. I exhibit to the Society a photograph of this palladium and of indium side by side. It will be seen that one form of hydrogen in indium has distinctly recorded itself on the plate, while that in palladium has not left a trace. I should add that the palladium was kept in a sealed tube till the moment of making the experiment, and that special precautions were taken to prevent the two pieces between which the arc was taken becoming unduly heated.

To sum up, then, the facts with regard to hydrogen; we have *h* differentiated from the other lines by its appearance alone in indium; by its absence during the eclipse of 1875, when the other lines were photographed; by its existence as a short line only in the chromosphere of the sun, and by the fact that in the experiments of 1869 a very high temperature was needed to cause it to make its appearance.

With regard to the isolation of the F line I have already referred to other experiments in 1869, in which Dr. Frankland and myself got it alone.[1] I exhibit to the Society a globe containing hydrogen which gives us the F line without either the red or the blue one.

[1] See also Plücker, *Phil. Trans.*, 1865, part 1, p. 21.

The accompanying drawing shows how these lines are integrated in the spectrum of the sun.

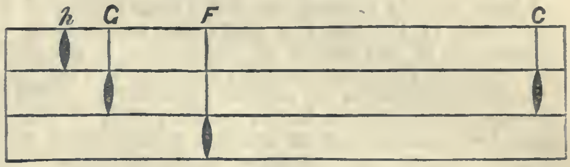

Fig. 6.

I have other evidence which, if confirmed, leads to the conclusion that the substance which gives us the non-reversed line in the chromosphere and the line at 1474 of Kirchhoff's scale, termed the coronal line, are really other forms of hydrogen. One of these is possibly more simple than that which gives us *h* alone, the other more complex than that which gives us F alone. The evidence on this point is of such extreme importance to solar physics, and throws so much light on star structure generally, that I am now engaged in discussing it and shall therefore reserve it for a special communication.

In the meantime I content myself by giving a diagram in which I have arranged the various groupings of hydrogen as they appear to exist, from the regions of highest to those of lowest temperature in our central luminary.

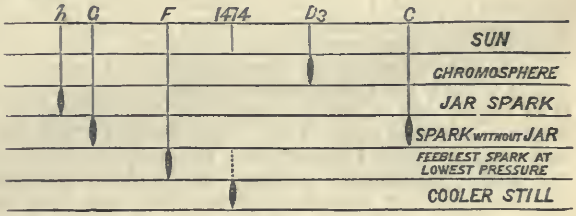

Fig. 7.

Summation of the above Series of Facts

I submit that the facts above recorded are easily grouped together, and a perfect continuity of phenomena established on the hypothesis of successive dissociations analogous to those observed in the cases of undoubted compounds.

The other Branches of the Inquiry

When we pass to the other possible evolutionary processes to which I have before referred, and which I hope to discuss on a future occasion, the inquiry becomes much more complicated by the extreme difficulty of obtaining pure specimens to work with, although I should remark that in the working hypothesis now under discussion the cause of the constant occurrence of the same substance as an impurity in the same connection is not far to seek. I take this opportunity of expressing my obligations to many friends who have put themselves to great trouble in obtaining specimens of pure chemicals for me during the whole continuance of my researches. Among these I must mention Dr. Russell, who has given me many specimens prepared by the lamented Matthiessen, as well as some of cobalt and nickel prepared by himself; Prof. Roscoe, who has supplied me with vanadium and cæsium alum; Mr. Crookes, who has always responded to my call for thallium; Mr. Roberts, chemist to the Mint, who has supplied me with portions of the gold and silver trial plates and some pieces of palladium; Dr. Hugo Müller, who has furnished me a large supply of electrolitically-deposited copper; Mr. Holtzman, who has provided me with cerium, lanthanum, and didymium prepared by himself; Mr. George Matthey, of the well-known metallurgical firm of Johnson and Matthey, who has provided me with magnesium and aluminium of marvellous purity; while to

Mr. Valentin, Mr. Mellor, of Salford, and other friends, my thanks are due for other substances.

I have already pointed out that a large portion of the work done in the last four years has consisted in the elimination of the effects of impurities. I am therefore aware of the great necessity for caution in the spectroscopic examination of various substances. There is, however, a number of bodies which permit of the inquiry into their simple or complex nature being made in such a manner that the presence of impurities will be to a certain extent negligable. I have brought this subject before the Royal Society at its present stage, in the hope that possibly others may be induced to aid inquiry in a region in which the work of one individual is as a drop in the ocean. If there is anything in what I have said, the spectra of all the elementary substances will require to be re-mapped, and re-mapped from a new standpoint; further, the arc must replace the spark, and photography must replace the eye. A glance at the red end of the spectrum of almost any substance incandescent in the voltaic arc in a spectroscope of large dispersion, and a glance at the maps prepared by such eminent observers as Huggins and Thalén, who have used the coil, will give an idea of the mass of facts which have yet to be recorded and reduced before much further progress can be made.

In conclusion I would state that only a small part of the work to which I have drawn attention is my own. In some cases I have merely, as it were, codified the work done by other observers in other countries. With reference to that done in my own laboratory, I may here repeat what I have said before on other occasions, that it is largely due to the skill, patience, and untiring zeal of those who have assisted me. The burthen of the final reduction, to which I have before referred, has fallen to Mr. Miller, my present assistant; while the mapping of the positions and intensities of the lines was done by Messrs. Friswell, Meldola, Ord and Starling, who have successively filled that post.

I have to thank Corporal Ewings, R.E., for preparing the various diagrams which I have submitted to the notice of this Society.

EXPERIMENTS IN ELECTRIC LIGHTING

MR. LOUIS SCHWENDLER, Superintendent Electrician of the Government of India, has been conducting a very careful series of experiments in London on electric lighting, with a view to decide upon the advisability of introducing this method of lighting into railway stations in India. He has just published a *précis* of his forthcoming report, and as the experiments were conducted on thoroughly scientific principles, and solely with a view to discover the most effective method, the results attained are extremely valuable, especially when so many systems are competing for public favour :—

First, with regard to quantity of light per unit of power, unit of speed, and unit of money (first outlay). To solve this question Mr. Schwendler tried four different dynamo-electric machines producing the electric current in *one* direction, viz., A, medium size, B, small; as supplied by Messrs. Siemens, Brothers, of London (construction :—Siemens, system :—Hefner von Alteneck). C, workshop pattern, as supplied by Messrs. Soutter and Lemonnier, of Paris (construction :—Gramme). D, with two sets of brushes as supplied by the British Telegraph Manufactory (construction :—Gramme). Mr. Schwendler finds these four machines all sufficiently practical for the production of the electric light, but, as a rule, the statements of their actual efficiency were not found to be in conformity with the results obtained from his own experiments. The quantity of light produced by these dynamo-electric machines had been over-rated, and the amount of power consumed underrated. But, notwithstanding this, he finds that the unit of light as produced in the electric arc (disintegration) by any of the four dynamo-electric machines is at least fifty times cheaper than the unit of light as produced by combustion, considering the expenditure of power only. This represents an enormous engineering margin in favour of the electric light.

Mr. Schwendler makes a most important proviso by stating that this relation only holds good as long as *one* dynamo-electric machine produces *one* electric light; he returns to this point in a subsequent part of his careful *précis.*

The three dynamo-electric machines B, C, and D, he found practically equal; the dynamo-electric machine A gives a much stronger light for a comparatively smaller expenditure of power. In round numbers it may be said that dynamo-electric machine A gives about double the quantity of light given by any of the other three machines, and that only about half as much power is expended to produce the unit of light. This favourable result, Mr. Schwendler states, is principally due to the comparatively small internal resistance of A, and its low speed.

Secondly, with reference to constancy and regularity of the electric light, Mr. Schwendler says that this appears to be still the weak point, and many improvements in this respect are possible and desirable. He has tried two different lamps :—*a.* The Serrin lamp, as supplied by Messrs. Soutter and Lemonnier, of Paris, and the British Telegraph Manufactory; *b.* The Siemens lamp, as supplied by Messrs. Siemens Brothers. The Serrin lamp, for any given adjustment, regulates the length of the arc only in *one* direction, *i.e.*, it diminishes that length. The actual consumption of the carbon points regulates the length of the arc in the other direction, *i.e.*, increases it. In the Siemens lamp the decrease of the length of the arc is effected exactly in the same manner as in the Serrin lamp, but the increase in the length of the arc is not only left to the consumption of the carbon points—a comparatively slow process—but is accelerated by the addition of a make and break arrangement, which separates the carbon points. Hence, from a theoretical point of view, the Siemens lamp is undoubtedly superior, since the length of the arc is rapidly adjusted in both directions, and consequently the working currents can increase to a very considerable degree without spoiling the dynamo-electric machine. But practically Mr. Schwendler finds the Siemens lamp somewhat difficult to manage, and although, when *once* well adjusted, it burns as regularly as the Serrin lamp, it is far more difficult to arrive at this adjustment. For practical use he prefers, therefore, the Serrin lamp, with those alterations and constructional improvements which his own experiments have suggested. A second cause of the irregularity of the electric light is the still imperfect state of the carbon points. Of late some great improvements have been made in the manufacture of artificial carbons, but much more is required, and this point deserves the closest attention. In his final report Mr. Schwendler will treat this subject in detail. To make the electric light more steady, Mr. Schwendler states, should be considered one of the most important questions to be solved.

Thirdly, Mr. Schwendler considers the question as to how to put up the light, its position, and mechanical details. Under this head he considers the method of dividing the electric light, *i.e.* producing by the *same electro-motor* a number of lights at different points of a given space. This method, which he does not consider as yet solved, appears to him impracticable from an engineering point of view. He refers to the immense loss of strength in thus dividing the light, increasing in enormous proportion with the increase of sub-division. Mr. Schwendler, after his careful, severe, and long-extended trials, comes to the decided conclusion that the electric light can alone compete with light produced by combustion, when produced of great intensity in *one*

point by *one* dynamo-electric machine. Endeavours to cut up the electric light into a large number of small lights, although of great interest, must, he thinks, invariably result in engineering failure, as nobody could afford to pay for the luxury received. Thus, in the opinion of so competent a judge, all methods hitherto employed for using this method of lighting in public, are failures, involving a waste of power and money, with inadequate result. Having satisfied himself of the difficulty and impracticability of the division of the electric light, Mr. Schwendler tried diffusion, *i.e.*, a few large lights (each light produced by one machine) are placed at different points of the space, and by optical means the light is diffused over a large area. This method he finds perfectly practicable. There is naturally a large amount of light lost (by absorption), but, he states, this loss will bear a constant ratio to the total light produced, nay probably may decrease with the intensity. The actual plan by which Mr. Schwendler proposes to do it, and has done it during the trial, is to construct a silvered glass reflector in which a powerful electric light burns, throwing direct and reflected rays up to a white ceiling or any other convenient white surface. A number of such arrangements is to be put up in the most convenient places, and where they have the greatest effect. The form and size of each reflector will depend on the locality where it is to be used.

Any repairs required in course of time Mr. Schwendler believes can easily be effected by an ordinary mechanic. Only one man, he states, is actually required in each station, to take charge of the steam engine, dynamo-electric machine, lamps, and reflectors. Mr. Schwendler appends to this *précis* several details with reference to the adaptation of electric lighting to Indian stations, and also on some of the scientific results obtained by his experiments. Altogether his report is likely to be the most important contribution to a thorough knowledge of the public utilisation of electric lighting that has been made since the question has been resuscitated during the last year or two; and we should advise all interested in the subject to wait for his report before taking decisive steps to the adoption of any particular system.

NOTES

THE Emperor of Germany has approved of the election of Mr. Darwin and Prof. Owen as Foreign Members of the Berlin Academy of Sciences.

WE are glad to learn that M. Raoul Pictet is quite restored to health. The University of Geneva has conferred upon him the honorary degree of Doctor, and he has just been made a Chevalier of the Legion of Honour by the French Government, in recognition of his eminent services to science, and especially of his successful experiments in the liquefaction of gases.

A COMPETITIVE examination is going on at the Paris Conservatoire des Arts et Métiers, for the appointment of a professor of physics and meteorology at the National School of Agriculture. The examination has been conducted on a new principle by a jury presided over by M. Boussingault. Each of the seven candidates has expounded before the jury his programme of lectures to be delivered, and each of them has in turn delivered a lecture on physics, and another on meteorology, after a preparation of four hours. The competition is open to all without any condition of age, qualifications, and nationality; but the jurymen are instructed to attend, in giving their verdict, to the degrees obtained by candidates and their previous work or discoveries.

THE Municipal Council of Paris has voted a subvention of 2,000 francs to M. Joseph Vinot, editor of the *Ciel*, for a series of popular lectures on astronomy, to be delivered at the Salle des Écoles, rue d'Arras. Admiral Mouchez, who was present at the last lesson, announced to the pupils, numbering from 400 to 500 that he will take measures to admit them to the observatory *seriatim*, in order to initiate them into the use of the large astronomical instruments so ably described by their professor. In one of the last reports read before the Paris Municipal Council it was stated that it would be necessary to establish somewhere in Paris an observatory of popular astronomy entirely devoted to the public exhibition of celestial phenomena, other establishments being entirely devoted to investigation.

PROF. S. P. THOMPSON has reprinted his valuable address on "Technical Education," given at the Social Science Congress last October. In this time of intense depression, when trade seems to be drifting from our shores, and people are wondering how it is that other nations are outstripping us in departments that used to be considered as peculiarly British, Prof. Thompson's remarks on the ignorance of our mechanics are peculiarly appropriate. One telling instance he gives of the lamentable want of intelligent skill that prevails among workmen and manufacturers in this country:—"I was recently informed by Prof. Graham Bell that he is about to return to America to resume his researches in telephony, his principal reason for quitting his native shores once more being that he found himself, in this country, unable to get his ideas carried out, unable to procure workmen capable of comprehending and carrying out new ideas, such workmen, in fact, as he was able to employ during his four years' residence in America. He pointed to the laboratory of Mr. Edison as an example of an institution to which there is no parallel in this country, though there are several in the States, a laboratory equipped with a staff of trained workmen, Americans, Germans, or Englishmen, whose business is not to work on old lines, but to carry out and put into practical form new and untried devices. No wonder inventions multiply when inventors have so powerful an aid as this to further their designs; and, mark this, Mr. Bell returns to set up a similar laboratory because he cannot find in his native country men whose technical training would qualify them for his particular work." In a note Mr. Thompson gives the following paragraph from a letter of Prof. Graham Bell to a friend in America which has been going the round of the American press:—"If you want to know why inventors are more numerous in America than they are here, come and live for six months in England. If you wish to know how it feels to be brimfull of ideas, and yet to be unable to have one of them executed, come to England. If you wish to know how it feels to have to wait for a month to have the simplest thing made, and then be charged a man's wages for two months, come to England. You will here be unable to see the interior of a workshop or to come into direct contact with your workmen, and the people seem incapable of working except in the ruts worn by their predecessors. They are absolutely incapable of calculating any new design without the most laborious oversight from the inventor, and their masters, instead of encouraging invention, do all they can to put a stop to it by refusing admission to the workshops and charging the most exorbitant prices for experimental work, avowedly because 'they don't want such kind of work,' 'it gives more trouble than it is worth;' and 'if you must have new things made you must expect to pay for them!' It is in vain that I say I am willing to pay anything to have my work done, and that what I object to is having to pay for not having it done. It is the same everywhere. Not only is your work not done, but you have to wait so long for the simplest things that your ideas cool, and you get quite exasperated at your inability to do anything." The moral of all this is obvious.

THE widow of the late Prof. E. Eichwald has presented the remarkable palæontological collections of her husband to the St. Petersburg University, which already possessed a part of them. These collections, collected by the late Prof. Eichwald since 1825, number no less than 30,000 specimens of fossils from

the various formations of Western Europe, from the Petchora Land, from the Aleutian Islands, Siberia, Crimea, &c.; several European geologists as well as the late Mr. Peabody, have many times negotiated for the purchase of them.

ON December 22, Prof. Forster, Director of the Bern Observatory, gave to the Bern Economical Society a very interesting report on weather-warnings. After a sketch of the development of these warnings during past years in Europe, he pointed out the importance of the "Service Agricole," established between France and Austria, by which daily telegrams are sent, advertising the coming weather; 85 per cent. of these prognostications having been perfectly true, 7 per cent, approximately true, and only 8 per cent. untrue. As to the introduction of such a service in Switzerland, it would meet with great difficulties because of the great variety of topographical features of the country and of the incomplete knowledge of the local climatic conditions. These last having been, however, carefully studied since 1864, the first steps towards the establishment of such a service were recently made by the Swiss Meteorological Commission, some of whom wished to undertake immediately to introduce weather warnings into Switzerland, whilst the majority of the Commission was for the adjournment of them for one or two years. The Society expressed their desire for the introduction of weather prognostics as soon as possible, and we may hope that shortly Switzerland also will have its weather warnings.

The Association Scientifique de France will commence at the Sorbonne its series of lectures for 1879. On January 16 M. Milne-Edwards, president of the Association, will be in the chair. M. de Lesseps will lecture on Central Africa. The lecture will be illustrated by dissolving views made with drawings sent by Gordon Pasha from the newly-annexed Egyptian provinces.

THE *Reale Istituto Lombardo di Scienze e Lettere* has recently published a list of subjects for prizes to be awarded in this and following years. Among these subjects are the following:—Nosological geography of Italy; critical history of the telephone; on the nature of miasma and contagion; on the direction of balloons; is the generative material of hydrophobia a virulent principle or an organic germ? history of the progress of anatomy and physiology in the present century, especially with regard to the doctrine of Gall; illustration of some facts of the macro- or microscopic anatomy of the human brain; motor centres of the cerebral system; statistics of motor force, hydraulic and steam, in and around Milan.

THE Borough engineer of Liverpool has issued a not very encouraging report on the result of his visit to Paris for the purpose of examining the systems of electric lighting in use there. They are much more expensive than gas in Liverpool, and more than 50 per cent. of the light is absorbed by the globes used. Nevertheless he recommends a trial in Liverpool to find if no more economical method can be discovered. We recommend to him a perusal of Mr. Schwendler's report referred to elsewhere.

WE have received from Spain two numbers of a fortnightly scientific journal, published at Barcelona, which we welcome as a hopeful sign of progress in that country. The *Crónica Científica*, as the journal is called, while containing considerable extracts from foreign journals, and reports of foreign science, has a fair proportion of original contributions from Spanish investigators.

WE have received the number of the *Anales* of the Argentine Scientific Society for November. Among the papers is the continuation of M. Carlos Berg's monograph on the *Hemiptera argentina*, and a paper by Dr. D. Tomás Peron on the bark of Quebracho Blanco (*Aspidosperma quebracho*). Among the honorary members of this Society we notice the name of "Dr. Carlos Darwin;" while "Juan Lubbok, Londres," is a corresponding member.

IN connection with the Yorkshire Naturalists' Union, a "Grand Exhibition" of natural history specimens and scientific apparatus will be held from January 10 to 16 at the Mechanics' Institute, Leeds. On January 10 the Exhibition will be opened by the President of the Union, Mr. H. C. Sorby, F.R.S. The exhibition will be opened every succeeding day from 10 A.M. to 10 P.M., and will include in the various departments of natural history a large number of objects, including some of the finest private collections in the county, whilst the Physical Science Department will contain all the latest scientific novelties, including the apparatus for the liquefaction of oxygen, &c. There will also be a quantity of apparatus seldom exhibited to the public, together with instruments used in important original researches. Every evening a series of demonstrations and short addresses, and selections of music will be given. Microscopes and aquaria will be constantly on view. In the basement will be shown the process of manufacture of scientific apparatus. Although the announcement of this exhibition smacks a little too much of Barnum and the penny show, still the exhibition and lectures seem likely to be productive of permanent good in the district.

THE International Piscicultural Exhibition which will take place at Berlin in the spring of next year promises to be extremely interesting. A number of English, Russian, American, and even Japanese and Chinese exhibitors have already promised to take part in it. The Crown Prince of Germany has undertaken the protectorate of the exhibition and takes a great interest in its success.

HERR C. RECLAM has recently made a detailed report of the first cremation which took place at Gotha a short time ago. He calculates the cost of each cremation at about 4*l.*, which in case the furnace is in continual use, so that between two processes it has not time to cool, would be reduced to 3*l.* It is hoped in Germany that the example of Gotha will soon be followed by other cities so that Milan and Gotha will no longer be the only cities where cremation takes place.

PROF. ASA GRAY, we learn from *Harper's Weekly*, announces the detection, after the lapse of a hundred years, of a plant obtained by Michaux in the mountains of North Carolina, and known as the *Shortia galacifolia*, the re-discovery also having occurred in M'Dowell County, in North Carolina, in a region east of the Black Mountains.

Science News for December 15 contains some "Later Notes on Texan Birds," by George B. Sennett, the result of a second journey to south-western Texas made last spring. The Notes chiefly refer to nesting habits of the more peculiar forms. The region was on the banks of the Rio Grande within a few miles of its mouth, with Lomila Ranche as the central point.

"VÖGELBILDER aus fernen Zonen" is the title of an atlas of foreign birds just published by Fischer, of Cassel, under the care of Dr. Ant. Reichenow. The first part, before us, contains three beautifully coloured plates of birds, artistically grouped amid suitable surroundings, each plate having explanatory text, in which each species represented is pretty fully described, giving not only the scientific but also the native, German, French, English, and other names of the birds. The three plates are devoted to parrakeets and allied kinds. The same publisher sends us a series of large zoological wall-plates, admirably adapted, it seems to us, to teaching zoology in a thoroughly scientific manner. The plates sent us are mainly

devoted to the lower forms, the specimens selected being enormously magnified, coloured, and exhibiting all details both of external and internal structure.

"THE Year Book of Facts in Science and the Arts," edited by James Mason (Ward, Lock, and Co.), is little better than a scrap-book of cuttings from various papers; we don't suppose it is seriously intended to represent the science of the past year.

MESSRS. HARDWICKE AND BOGUE have issued a second edition, "revised and corrected," of Mr. M. P. Edgeworth's work on "Pollen," noticed in our columns on its first publication (NATURE, vol. xvi. p. 499).

AT the last meeting, December 6, of the Russian Geographical Society, Col. Rykatchoff made a communication on the difficulty of organising observations on rain and storms.—Prof. Meller made a very interesting communication on the former connection between the Sea of Azov and the Caspian. The character of the geological formations on the tract between both seas proves without doubt that during the tertiary epoch the waters of both were connected; thus organic remains of Caspian origin are found within eighty-seven miles from the actual shores of the Sea of Azov.

AT the last meeting of the St. Petersburg Physical and Chemical Society, Prof. Beketoff made a communication on the atomic heat-capacity of hydrogen when mixed with palladium. He determined it as equal to 5·86, *i.e.*, very near to that of copper and silver.

THOSE of our readers who are in the habit of using chemical apparatus should get the Revised List just issued by Mr. Fletcher, of Warrington, who deserves credit for the very successful efforts he makes to introduce improvements into this department.

THE much-talked-of canal between Delaware and Chesapeake Bays, which will shorten the water-route from Baltimore to New York and Europe by 225 miles, is now at last to be constructed. Its length will be seventeen miles, and the cost is estimated at four million dollars. It will run through the Sassafras Valley and will have no locks.

THE additions to the Zoological Society's Gardens during the past week include a Punjaub Wild Sheep (*Ovis clyclōceros*) from India, presented by Col. W. R. Alexander; two Californian Quails (*Callipepla californica*) from California, presented by Mr. William Turquand; seven Brown Tritons (*Geotriton fuscus*), South European, presented by Prof. H. H. Giglioli, C.M.Z.S.; a Feline Dowrocouli (*Nyctipithecus felinus*) from South America, purchased.

FURTHER RESEARCHES ON THE SCINTILLATION OF STARS

SINCE last we reviewed M. Montigny's valuable researches on the scintillation of stars (vol. xviii. p. 292) he has again published some highly interesting details. The researches now in question refer specially to the changes of colour which characterise the scintillation of the *red* and *orange* stars. M. Montigny tried to solve the question whether the changes of colour in scintillation follow certain definite laws; whether, for instance, their relative frequency expressed in numbers, shows differences which depend on the nature of the star's own light, on the star's elevation above the horizon, or on the condition of the atmosphere.

In order to solve this complicated question, it was divided into its several parts. First of all M. Montigny investigated the influence of the star's own light and that of the condition of the atmosphere upon those colours which characterise the scintillation of the stars of the so-called third type. Our readers will remember that these are the stars which show black lines as well as dusky bands in their spectra; they are generally of a red or orange colour, and mostly variable. There are not many fine stars in this class, the most remarkable ones are about thirty in number, and M. Montigny has examined only the following fifteen:—β Andromedæ, α Ceti, ρ Persei, Aldebaran, Betelgeuze, α Hydræ, Arcturus, δ Virginis, δ Coronæ, α Serpentis, Antares, α Herculis, γ Aquilæ, and β and ϵ Pegasi. The evenings of observation now number 476, and reach from October, 1870, to February, 1878.

The way in which the observations were made was the following:—After each evening of observation not only the values for the intensity of scintillation were entered for each star, reduced to a distance of 60° from the zenith, but each single colour observed in the circular image was also noted down. Further, the observations made in wet weather were noted separately from those made during dry weather. Finally the various colours were entered on a table divided into seven columns, respectively headed—red, orange, yellow, green, blue-green, blue, and violet. The sum total of any column thus indicates the number of times which the colour in question was observed in a certain star. Arcturus, for instance, in 131 observations during moist weather, showed the red colour 130 times and blue 118 times. These numbers thus express the absolute frequency of these two colours. If we compare the number 130 for red, with the sum total of all colours shown by Arcturus during rainy weather, which is 491, then we obtain the relative frequency of red, which is 0·265, or multiplied by 1000 = 265. Therefore in 1000 changes of colour which appeared in Arcturus during rainy weather, red occurred 265 times, and blue 240 times.

In the following table we give the average frequencies of the different colours for the fifteen stars of the third type enumerated above; line A shows the frequencies observed in rainy weather, and B those observed in dry weather. The total of observations was 800 for A and 368 for B; the totals of the changes of colour observed were 2,982 for A and 1,368 for B.

	Intensity.	Red.	Orange.	Yellow.	Green.	Blue-green.	Blue.	Violet
A ...	60	272	194	239	57	4	230	3
B ...	43	278	213	222	63	5	216	4
Average	52	275	204	230	60	5	223	4

We observe in this table that (1) the relative frequency of red is far greater than that of any other colour in rainy weather as well as in dry; (2) red, green, and particularly orange are seen more frequently in dry weather than in wet; (3) the frequency of yellow and blue is on the contrary greater in wet weather than in dry.

Although the differences in the frequency of one and the same colour, according to the state of the atmosphere, are rather limited, they nevertheless indicate an important fact. It is also remarkable that the numeric differences in the complementary colours red and green on the one hand, and blue and yellow on the other, lie in the same direction. It is further worthy of notice that the greater frequency of blue in rainy weather agrees well with the fact that blue greatly predominates during such weather in the image of the star as shown by the scintillometer. This predominance of blue has also been frequently observed a short time previous to rainy weather.

The following table will be found interesting, as it contains the changes of colour and intensity of scintillation of the six brightest stars of the third type. In line I. are those of Betelgeuze, which is orange coloured, and the spectrum of which shows numerous broad bands, dissolvable into lines; line II. gives those of Aldebaran, pale red, whose changing spectrum has many well-defined lines and dark bands; line III. represents Arcturus, yellow-orange, with numerous dark lines not united into bands in its spectrum; line IV. gives those of α Hydræ, a yellow star with very dark lines in the spectrum; line V. those of Antares, red, with wide bands and very distinct lines; and line VI. those of α Herculis, yellowish red, with black lines and dark bands.

	Intensity.	Red.	Orange.	Yellow.	Green.	Blue.	Violet.
I. Betelgeuze ..	65	255	190	234	106	202	13
II. Aldebaran ...	62	255	186	232	104	210	13
III. Arcturus ...	61	253	120	246	130	219	32
IV. α Hydræ ...	55	284	162	253	113	188	—
V. Antares ...	53	266	121	245	130	219	33
VI. α Herculis ...	47	275	225	232	51	217	—
Average	57	265	167	240	106	209	15

These values show that the relative frequencies of the three principal colours, red, orange, and blue, remain within narrow limits for the six stars. Yet red seems to increase in frequency in the three last stars, two of which are of a decided red tint,

and whose intensity of scintillation is far smaller than that of the other three. With regard to the effect of the star's own colour it must be remarked that the relative frequency of that colour or of a nearly related one is often very great; thus, for instance, yellow is very frequent in the yellow star α Hydræ, and orange in the orange stars Betelgeuze and α Herculis. The total number of observations M. Montigny made of these six stars was 574.

For the sake of comparison M. Montigny has calculated the relative frequency of colours in two stars of the second type, to which, as our readers will remember, our own sun belongs too. The stars selected were Pollux, with a very characteristic spectrum, and Capella, which scintillates with great regularity. Both stars are yellow and their spectra show very thin dark lines. The average frequency of colours for these two stars is given separately, A in rainy weather, and B in dry weather, from a total number of 267 observations of Capella and 116 observations of Pollux.

	Intensity.	Red.	Orange.	Yellow.	Green.	Greenish blue.	Blue.	Violet.
A ...	88	281	88	280	86	7	250	8
B ...	63	299	41	304	122	26	194	14
Average	76	290	65	292	104	17	222	11

If we compare these results with the former ones we find the frequency of red and particularly that of yellow to be considerably greater in Capella and Pollux than in stars of the third type, while the frequency of orange is very much less, having decreased from 204 to 65. The influence of the weather was equally apparent in these stars; in dry weather red was more frequent, and in rainy weather blue. The relative values of green and violet are greater in these two stars than in the fifteen stars of the third type; probably these colours will become more important when the observations are extended in a larger measure to the stars of the two first types.

It is therefore proved beyond doubt, by the results above mentioned, that the changes of colour which characterise the scintillation of stars, are subject to general laws which are quite as regular and fixed as those which govern the changes in the intensity of the phenomenon as we pass from one type to another, or under the influence of rain and fine weather.

In one of the last numbers of the *Bulletin* of the Brussels Royal Academy of Sciences M. Montigny publishes the results of some researches concerning the influence of the aurora borealis on the scintillation of stars. We may return to this subject at a future date.

NOTES FROM NEW ZEALAND

MR. T. H. POTTS, of Ohinitahi, N.Z., sends us the following notes:—

Which Species of Pinus have Cones really Sessile?—In working up the habits of a collection of pines one has felt a difficulty in understanding why certain cones should be termed sessile; for example, the cone of *P. tuberculata* is described by Gordon in his "Pinetum;" also by Broun, in his "Forester," as "quite sessile." Why? Can such a description be correct at its early stage of life? It is then perched on a scaly foot-stalk, well developed; months elapse, its increasing bulk is protected with needle-pointed scales, its foot-stalk becomes curved, but is plainly visible; the mature cone, grey and glossy, clings tightly to its stem, it can scarcely be removed therefrom without tearing off a shell of bark adhering to the nasal scales; when wrenched off it shows a portion of its curved foot-stalk that has been embedded in the growing stem.

A very similar habit may be observed in *P. insignis.* Should not the cones of *P. tuberculata* and those of other species showing a similar habit, be described rather as *apparently sessile* than as "quite sessile"?

It may be mentioned that here *P. tuberculata* bears cones not only on the stem and main branches, but also on the soft green shoots of the outer branches, this would in part account for the foot-stalks becoming embedded in the growing bulk of the shoot.

P. insignis here bears cones of longer dimensions than those given by the authors before named; five specimens measure rather over seven inches in length, with a circumference of eleven inches.

Heredity.—One of my sons returning from a visit to the Chatham Isles, brought back with him a young pup of a famous colly breed. As soon as it was grown enough to run about it displayed an unusual excitement in the presence of horses by jumping upwards repeatedly towards their heads. As this trick or vice was unknown or unpractised by any of our dogs, it was, of course, soon remarked. On inquiry of a Chatham Island settler, I found this was a common trick in the colly family "Bell" sprang from; so Bell faithfully held to the habits of her race.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE following programme of the Natural Science Courses in Trinity College, Dublin, may be of interest to our readers:— In the Junior Sophister year natural science is represented by two courses—one in zoology, the other in botany. Students attending a course of lectures in natural science are examined three times during the term on the subjects of the lectures, and no student is allowed credit for his attendance who does not answer sufficiently. In the Senior Sophister year natural science is represented by one course in geology. In each term examinations are held of those students in the Junior and Senior Sophister classes who are qualified to become candidates for honours. At the Michaelmas examination in the Junior Sophister year prizes of 4*l.* and of 2*l.* are awarded by the Board, on the recommendation of the Honour Examiners, to the best answerers among the candidates. At the Hilary and Trinity examinations of the Junior and Senior Sophister years honours without prizes are awarded—of which honours there are two ranks. At the Michaelmas examination of the Senior Sophister year, examinations for Moderatorships are held. The Senior Moderators receive gold medals, and the Junior Moderators silver medals, which are given to them publicly before the University, by the Chancellor, at the commencements, when they are admitted to their degrees. The First Senior Moderator receives a large gold medal if specially recommended by the Court of Examiners. The subjects of examination for the Moderatorships in natural science are the following, each of which has equal weight:— 1. Physical Geography, Geology, and Palæontology. All the ordinary and honour courses of the Sophister years. A limited course to be announced each year. Course for 1879:—The Silurian Period. 2. General and Physiological Anatomy. A limited course to be announced each year. Course for 1879:— Circulation and Respiration. The Circulatory and Respiratory Organs in Mammals. The Respiration and Assimilation in Plants. 3. Zoology and Botany. All the ordinary and honour courses of the Sophister years. A limited course to be announced each year. Zoological Course for 1879:—The Non-Placental Mammals. Botanical Course for 1879:—The Fucoids. The Professors of Zoology, Botany, and Geology, give each a course of demonstrations and a course of lectures in each term, especially meant for Junior Sophisters. The Museum of Comparative Anatomy and Zoology is open, under the superintendence of the professor, to all students, to whom every facility is given for the prosecution of their studies. For the purposes of study fresh specimen of plants are, under the superintendence of the professor, to be had by the student from Mr. Frederick Moore, at the College Botanical Gardens, at Lansdowne Road; and a large number of mounted specimens of cryptogamic plants are also to be seen and examined in the herbarium. The Museum of Geology and Palæontology is open to the students attending the course.

THE Science and Art School of St. Thomas' Charterhouse Institution, Goswell Road (the largest in the United Kingdom), under the direction of the vice-chairman of the London School Board, commenced a new term on Monday evening the 6th inst. Since the commencement of the present session upwards of 600 of our elementary school teachers of London have taken advantage of the privileges offered by the classes. The attendance at the classes for experimental work in chemistry and physics has been very large.

SCIENTIFIC SERIALS

Journal of the Franklin Institute, November, 1878.—Some time ago Prof. Thurston invented apparatus for re-determining the coefficients of friction of lubricated surfaces, and the laws governing such friction, for a wide range of temperatures, pressures, and velocities. The machines have been in use about five

years, and have furnished much useful information, some of which is here embodied in the opening paper.—Mr. Cooper investigates the driving power of leather belts.—Prof. Chase gives a series of verifications and confirmations of astronomical hypotheses and predictions, and a brief statement of the principles on which they are based.

Journal de Physique, November, 1878.—In a contribution to the theory of vowels, M. Bourseul, after pointing out that there are really as many distinct vowels as there are pitches of sound proper to the mouth, enumerates the vowels (ten in number) which he uses in speaking French. On examining the sounds of the mouth-cavity which correspond to them (apart from absolute pitch), he finds they fall into two divisions, one being in perfect accord with *do* major (*mi, do, sol, mi, do*), the other with *re* (*fa, si, re, fa, si*). This confirms in an unexpected way a principle discovered by the philologist, M. Rœhrig, in 1848. He noted the marked difference, or rather antagonism, of certain consonants and certain vowels, and he arranged the latter in two distinct classes, one comprising *a, o, ou*, the other *é, eu, u*. When studying the Tartar and Finnish tongues, he remarked that the vowels in a word of Tartaro-Finnish idiom were invariably of the same class. The derived languages have undergone alterations, whereby the traces of this original principle gradually disappears, still it may be recognised.—With regard to vibratory forms of liquids on circular metallic plates, M. Decharme finds that the widths of the striæ are inversely proportional to the square roots of the numbers of vibrations of the corresponding sounds.—Prof. Crova explains his important mode of comparison of the radiations emitted by calorific and dark sources; and in their continued paper of experimental researches on magneto-electric machines, MM. Mascart and Angot take up mixed machines, *i.e.*, those composed of magnets and electro-magnets.

December, 1878.—M. Deprez here describes the way in which he solves a problem relating to the work of steam in locomotive cylinders, viz., to trace, at a distance, a curve whose abscissæ and ordinates are respectively proportional to the path traversed by the piston and the pressure exercised by the steam on the piston. The solution rests on two principles—(1) Giving the sheet of paper (for the curve) a motion rigorously proportional to that of the piston; (2) Measuring at a certain point and *instantaneously*, the pressure of the steam on the piston.—M. Terquem communicates a paper on the use of plane liquid sheets (from bars and connecting threads) for experimental demonstration and measurement of the superficial tension. The determination in this way agrees with that by observation of the ascent of liquid in a capillary tube, whereas the process of counting drops gives perceptibly higher numbers.—M. Macé du Lépinay studies mathematically the subject of potential in electrodynamics and electromagnetism.

Verhandlungen des naturhistorischen Vereines der preussischen Rheinlande und Westphalens, thirty-fifth year, vol. v. part 1. (Bonn: Max Cohen and Son, 1878.)—Dr. Franz Leydig, herpetological reminiscences of Roesel von Rosenhof. Roesel was born in Nürnberg, 1705, and died there in 1759, and he wrote on amphibian reptiles, insects, crustacea, and spiders, worms and polyps, rotifers and infusoria.—Dr. Förster, a short monograph of some parasitical hymenoptera, in which many new genera and species are described.—P. Hesse, contribution to the molluscan fauna of Westphalia.—Dr. Theodor Wolf, on Cotopaxi and its last eruption on June 26, 1877, with two plates.—Dr. A. von Lasaulx, contribution to a knowledge of the igneous rocks (Eruptiogesteine) in the districts of the Saar and the Mosel, with two plates.

Reale Istituto Lombardo di Scienze e Lettere, Rendiconti, vol. xi. fasc. xvi. xvii.—This contains reports connected with the award of prizes, announcement of subjects for new prizes, &c.

Fasc. xviii.—On the integration of algebraico-differential equations of the first order and degree by means of linear functions, by Prof. Casorati.—On the dominant diseases of vines, by Drs. Garovaglio and Cattaneo.

SOCIETIES AND ACADEMIES

London

Royal Society, December 19, 1878.—"On the Chemical Composition of Aleurone Grains," by S. H. Vines.

In the first part of the paper an account is given of some experiments confirming those of Weyl (*Zeitschr. f. physiol. Chemie*, Bd. i.), which show that the reserve-proteids are stored up in the seeds of the blue lupin in the form of globulins (vitellin and myosin), and that the conglutin extracted from them by Ritthausen is a product of the alteration of these globulins by the reagents used in the process of extraction. Mr. Vines' micro-chemical observations further show that these globulins constitute the aleurone-grains.

In the second part Mr. Vines points out that, in addition to the globulins, the aleurone-grains contain a proteid which is soluble in distilled water. Such a solution of this substance does not become turbid in boiling; it gives a precipitate on the addition of a drop of nitric acid, soluble in excess; it gives the xanthoproteic and Millon's reactions; it gives an immediate precipitate with acetic acid and potassic ferrocyanide; and it gives a bright pink colour when treated with excess of strong caustic soda on the addition of a drop of dilute solution of cupric sulphate. This substance does not dialyse. These properties show that it belongs to the group of the peptones, and that it most resembles the *a* peptone of Meissner, or, adopting Kühne's nomenclature, hemialbumose, a name which may be provisionally applied to this substance also. The discovery of this substance is of interest in connection with the researches which have been made during the last few years into the existence of peptic ferments in the seeds and other parts of plants.

Linnean Society, Dec. 19, 1878.—Prof. Allman, president, in the chair.—A note on South African orchids, by W. Mansell Weale, was read by the secretary, and a series of drawings illustrating the above, and also other plants from the same region were likewise exhibited on the part of Mr. Weale. He points out that the supposed generic characters of *Mystacidium* and *Polystachyon*, founded on the "two-legged" caudicles of the pollinia, are fallacious.—In a short paper consisting of a description of some rare shells, by Mr. Sylvanus Hanley, *Melania Limborgi*, from British India, and *Leptomya gravida*, of uncertain habitat, were specially referred to as being unusual in several respects.—An interesting communication on the relations of *Rhabdopleura* was made by the president.—Messrs. F. M. Campbell, J. L. Hamilton, and J. J. McAndrew were elected Fellows of the Society.

Entomological Society, Dec. 4, 1878.—Mr. H. W. Bates, F.L.S., F.Z.S., president, in the chair.—The following elections took place: Mr. T. P. Newman as a Member, and Mr. J. Walker, R.N., as a Subscriber.—Mr. Stainton exhibited a series of specimens of *Glyphipteryx schœnicolella* taken by Mr. Threlfull near Witherslack.—Mr. Wood Mason exhibited and made remarks upon a stridulating beetle belonging to the *Rutelidæ*.—Prof. Westwood exhibited some insects and diagrams illustrative of so-called monstrosity, and contributed remarks thereon.—Mr. McLachlan exhibited a series of cases of the larvæ of Trichopterous insects forwarded to him by Dr. Fritz Müller of Santa Catharina, Brazil, one of which, Dr. Müller stated, had the peculiar habit of living on trees in the water that collects between the leaves of *Bromeliæ*, in which tadpoles, the larvæ of dragon-flies and other aquatic animals were also to be found. Mr. Bates stated that rain-water collects at the bases of the leaves of these plants and remains there for nine months out of the twelve. Dr. Müller had also forwarded a photograph of a number of cases which he considered to belong to some species of *Hydropsychidæ*, and in his own words, "make a funnel-shaped entrance to their houses with a net of which no spider need be ashamed." In reference to the opinion of Dr. Müller as to the homologies which appeared to exist between the neuration of various *Lepidoptera* and that of *Trichoptera*, Mr. McLachlan expressed his own belief that in a linear arrangement the orders *Lepidoptera* and *Trichoptera* should not be widely separated.—The Rev. A. Eaton exhibited a piece of "Kungu cake" from Lake Nyassa district, where, according to Livingstone and others, it is used extensively as food by the natives, who manufacture it from large quantities of a minute insect, conjectured to be a species of *Ephemeridæ*. From an exhaustive examination, however, Mr. Eaton found it to be a minute representative of the *Culicidæ*, probably belonging to the genus *Corethra*. In connection with the subject of insect-food as used by man, Mr. Distant remarked, he had learned from Mr. Chennell that *Erthesina fullo*, a very common eastern hemipterous insect was largely eaten by the Naga Hill tribes of North-eastern India.—Mr. Meldola in reply to some queries forwarded to him, as to the chemical composition of the bodies of insects, remarked that

the chitine, which comprised the horny external portion of the bodies of insects had been shown by analysis to contain about 6 per cent. of nitrogen; and as regards phosphates, Mr. Wm. Cole had burned some insects and found phosphoric acid in the ash.—Mr. Waterhouse forwarded for exhibition a living *Curculio*, found in an orchid house at Windsor, which was identified as one of the *Calandridæ*.—The Secretary read the report of the sub-committee appointed to consider the communication from the Board of Trade regarding the ravages of *Anisoplia austriaca* at Taganrog.—Mr. Butler communicated a paper on a collection of Lepidoptera from Cachar, North-east India.

Photographic Society, December 10, 1878.—James Glaisher, F.R.S., in the chair.—Papers were read, by Henry Cooper on a really reliable dry-plate process, by L. Warnerke on a case of the destruction of the latent image on washed emulsion, and its restoration, by W. Willis, jun., notes on the platinotype process, and by Edwin Cocking on the subjective and objective of pictorial photography.—Mr. Willis, in demonstrating his new platinum process, stated that ferric oxalate is sensitive to light, and then becomes ferrous oxalate; this, when dissolved in a hot solution of potassic oxalate, reduces the metal from chlorides and other salts of platinum. A sheet of paper is coated with a solution of ferric oxalate and potassic chloro-platinite, and then exposed to light under a negative; this produces a visible brownish ferrous image; it is then floated for a few seconds upon a hot solution of potassic oxalate and potassic chloroplatinite, the ferrous image becomes dissolved, and the combination thus formed reduces the platinum salt and forms the ultimate picture in metallic platinum.

Vienna

Imperial Academy of Sciences, November 14, 1878.—The following among other papers were read:—On a meteoric stone which fell at Dhulia, Hindostan, in November, 1877, by Dr. Brezina.

November 21, 1878.—On the behaviour of halogen derivatives of aromatic bodies towards water and lead oxide, by Professors Lippmann and Schmidt.—On the Clintonite group, by Prof. Tschermak and Herr Sipörz.—On the meteorite fall of Tieschitz, by Prof. Tschermak.

Paris

Academy of Sciences, December 30, 1878.—M. Fizeau in the chair.—The following papers were read:—Reply to M. Berthelot, by M. Pasteur. M. Trecul made some observations on the subject.—Borings undertaken by M. Roudaire, in view of the formation of an interior African sea, by M. de Lesseps. M. Roudaire writes on December 11, 1878, that having reached a depth of 18 metres, nothing but sand and water had been met with (no rocks). An explanation is offered of the exceptional tide of 2·50m. in the Gulf of Gabes.—M. Daubrée presented a map of the itinerary of Prof. Nordenskjöld in the glacial sea of Siberia, from August 7 to 27 last.—M. Cahours presented the three first vols. of the fourth edition of his treatise on general elementary chemistry. He indicates the additions and alterations made.—Report on the diplograph of M. Recordon, and his apparatus for use of the blind. This diplograph enables the blind person to produce ordinary writing and a seeing person to produce mechanically the characters the blind person can understand. It consists chiefly of two discs carrying respectively the signs and characters, and which are simultaneously applied to two sheets of paper, impressing the letter recognised by touch or by sight. M. Recordon is making a musical diplograph.—Harmotome and stilbite, by M. Gaudin. This is a study in atomic composition and arrangement (the two minerals contain 179 and 175 atoms respectively).—On electrochemical actions under pressure, by M. Bouvet. The decomposition of water by a current is independent of pressure. The quantity of electricity necessary to decompose a given weight of water is sensibly the same, whatever the pressure at which decomposition occurs. Oxygen and hydrogen, whatever the pressure, are liberated with equal facility, and there are no secondary phenomena causing recomposition, &c.—On the decomposition, at ordinary temperature, of an alkaline silicate by a salt of alumina (artificial hydrophane), by M. Monnier.—Determination, by M. Eylden's method, of the motion of the planet 103 Hera, by M. Callandreau.—On an interpretation of the imaginary values of time in mechanics, by M. Appell.—On an intuitive law according to which is distributed the weight of a solid circular disc, supported by an elastic horizontal base, by M. Boussinesq. The charge supported by each element of the base is that which would be directly over this element if we supposed the total charge distributed uniformly over the convex surface of a hemisphere, having the same base as the disc.—M. Joubert acknowledged M. Becquerel's priority in the experiment of magnetic rotation of the plane of polarisation under the earth's influence. The account had escaped his notice.—On a very precise way of observing the contact between the mercury and the ivory point in the basin in Fortin's barometer, by M. Goulier. The author has adopted a method similar to that indicated by M. Le Chatelier many years ago.—On the use of the telephone and microphone for scientific researches, by M. Hughes. This shows how delicate a means of observation these two instruments afford in researches relating to very weak currents, such as those from movement of a magnet before a helix. Several experiments are detailed.—On a new electric lamp, by M. Ducretet. The chief feature of this is the use of a column of mercury in which are immersed one or several crayons; the difference of density produces a thrust, which brings the crayons constantly and regularly to their point of application in proportion as they are consumed. One part of them becomes incandescent. An equal resistance in the circuit is insured, whatever the length and consumption of the crayons.—On the existence and conditions of formation of oxide of nickel, Ni_3O_4, by M. Baubigny.—On the nitrates found in beets and some other roots, by M. Barral. The greatest quantity of nitre per cent. of dry matter is found in the largest beets, and also in those that have least sugar. Beet is thus often given injuriously to cattle. In carrots, potatoes, and hay, 1 cc. (at the most) of bioxide of nitrogen was got in treating 5 to 10 grammes of dry matter, whereas for various beets the quantity never came below 14 cc.—Inertia of derivatives of chromium compared with the action of vanadium on salts of aniline in presence of chlorates in printing with aniline black, by M. Witz.—Analysis of raw sugars and saccharine matters; determination of water and all salts with mineral bases and organic acids, by M. Laugier.—On the harmlessness of borax in conservation of meat, by M. de Cyon. In M. Jourdes' process the borax is sprinkled lightly on the surface, and the meat retains its nutritive value. Prof. Panum, of Copenhagen, has proved the innocuity of borax and boric acid in meat-preserving.—Researches on the physiological action of *maté*, by M. Couty. It excites only, or at least primarily, the sympathetic system in those organs that are most independent of the nerve-centres; such as the intestines, the bladder, the accelerating nerves of the heart.—Poison of serpents, by M. Lacerda. The poison of certain serpents contains figured ferments showing remarkable analogies to bacteria.—On the function of chlorophyll in green Planaria, by M. Geddes. The gases they give off in sunlight contain 45 to 55 per cent. of oxygen, the rest nitrogen; hardly any carbonic acid.—Geological observations on Majorca and Minorca, by M. Hermite.

THURSDAY, JANUARY 16, 1879

A SCOTTISH METEOROLOGICAL MOUNTAIN OBSERVATORY

IT is the opinion of those best versed in meteorological science, that much valuable information regarding the constitution of the earth's atmosphere, and the laws which determine the changes in the atmosphere, is to be obtained by observations at elevated stations. To quote the words of the distinguished French philosopher, Biot: "It is in the high regions of the air that meteors are formed, rain, snow, and hail. There the thunder rolls and the lightning traces its furrows. There the aurora displays its plume of light, and the aerolite shines and bursts. There are the upper currents which chariot the clouds. It is to these elevated regions that the inquirers of meteorological science ought to be directed."

For want of permanent stations at high levels, attempts have been made to explore the upper regions of the atmosphere in balloons. In the year 1862, Mr. Glaisher—at much personal peril—accomplished about thirty ascents with instruments which enabled him to ascertain with some precision the aerial temperature, humidity, clouds, and other phenomena, up to a height of several miles. More recently, Tissandier, in France, made twenty-four ascents in balloons, also with the result of obtaining valuable information on these points. Since February, 1877, Secretan, an enterprising optician in Paris, has been sending up small exploring balloons, for ascertaining the height of clouds and the direction of the aerial currents up to about 1,200 metres.

The value of the data obtained by these casual explorations has led meteorologists to a more systematic study of the upper regions of the atmosphere.

Thus Dr. Hildebransen of Upsala has been devoting himself to a study of clouds, to ascertain their altitude, movements, and shapes at different seasons; and he has recently issued a circular to meteorologists in other countries, pointing out the importance of the inquiry, and inviting co-operation.

It has been recently discovered in France, by observations at the Montsouris Observatory, that *dust* of various kinds is at most seasons of the year floating in the atmosphere, consisting of spherules so minute as to be discernible only by the microscope or by chemical tests: and that which so floats is not always the same in the higher as in the lower regions of the air. The bearings of this new information on epidemics affecting both animal and vegetable life is awakening much attention among continental physicists.

These remarks refer to the information afforded by meteorological observations at high stations regarding the constitution of the atmosphere or the ingredients existing in it. But there is another use to which high-level stations can be and are applied, viz., to furnish early intimation of changes in the weather. It appears from the observations made at the high-level stations of the Scotch Meteorological Society, that changes of temperature take place in the upper regions from twenty-four to thirty-six hours sooner than in the same district at ordinary low levels. Lately Prof. Loomis has been comparing the observations made at high-level and low-level stations in America, and he finds a considerable difference, not only in the speed and direction of the wind, but even in the barometric pressure.

In these circumstances it is not surprising that scientific meteorologists in all countries should in addition to low-level stations have made strenuous efforts to obtain also stations at high levels, and that they have been to a large extent successful. Thus in France two meteorological stations have lately been formed on the Puy de Dôme and the Pic du Midi, at heights respectively of 4,809 and 9,439 feet above the sea. In Austria Dr. Hann, one of the ablest European meteorologists, with Government aid, established a station in Upper Carinthia at a height of 8,000 feet above the sea. There are three stations in Italy, at heights respectively of 7,087, 8,343, and 8,360 feet above the sea, and a fourth is about to be established on Mount Etna, at the Casa Inglese, at a height of 9,652 feet above the sea. In Switzerland there is a station at the Hospice of St. Bernard, at 8,130 feet above the sea. In the United States the meteorological station at Mount Washington is 6,600 feet, Mount Mitchell 6,691 feet, and at Pike's Peak (Colorado State), 14,216 feet above the sea; all of these stations were established by the Government, which also supplies instruments and pays the observers, who are soldiers.

Such being the state of matters in foreign countries as regards high-level stations, what is the case in Great Britain?

It is believed that in England the highest meteorological station is 1,372 feet above the sea; and that in Scotland the two highest are, respectively, 1,334 and 1,450 feet. It is matter of regret that in both England and Scotland there should not be stations at higher points, seeing that there are in both countries favourable positions for such. That regret has been repeatedly expressed by authorities to whose opinion some regard might have been expected to be paid. In February, 1877, the president of the English Meteorological Society, in his address to the Society, pointed out that "the most obvious way of gaining a clearer insight into the condition and movements of the gaseous envelope of the earth, is by the establishment of observatories on isolated mountain peaks. The value of this arrangement had been practically recognised abroad, and might well be imitated on some of our highest hills, such as Skiddaw in the north of England, or on the western seaboard of Ireland or Scotland, where their fitness as outposts, for giving early indications of storms from the west, would soon be appreciated."

The suggestion of high-level stations has been repeatedly made by the Scotch Meteorological Society. Thus, in July, 1875, the Chairman of that Society, after alluding to the value of the observations at the American high-level stations, observed that, so impressed was the Society's Council with the importance of high-level stations, that, if funds were forthcoming, "probably the very first thing which the Council would endeavour to do would be to establish stations on the two highest points of Scotland, viz., Ben Nevis on the west coast, and Ben Macdhui on the east coast, and, by means of intermediate stations on the sides of these mountains, obtain, as suggested by Mr. Stevenson, vertical meteorological sections of the atmosphere."

Again, at a general meeting of the Scotch Society in July, 1877, the Chairman, in his address, renewed his reference to the desirability of a station on, at all events, Ben Nevis, and mentioned that Lord Abinger, the proprietor, having consented to the erection of a hut for the purpose, "the Society's Council would readily establish the station if it only had the requisite funds." Testimony to the value of high stations has in like manner been given by Mr. Robert Scott, the Secretary of the Government Meteorological Department.

Mr. Scott was the first and principal witness examined before the recent Government Meteorological Commission, and his opinion on the point of high-level stations is shown by the following questions and answers :—

Q. Has the Meteorological Committee felt it desirable to have stations at some higher levels in Great Britain?
A. Certainly they have.
Q. Have they thought of any particular plan?
A. They have had no money for it.
Q. Have they thought of any place if they had money?
A. I may mention Settle, because there is a telegraph station there, a high-level station, about 1,000 feet above the sea, on the borders of Yorkshire and Lancashire. If ever we had 30*l.* a year to spare, we should like to have a station there. It is found in cold weather that warm weather sets in at the upper stations perhaps one or two days before it comes down.

When such are the opinions which have been expressed and brought before the country by authorities deserving of respect and attention, it is hoped that the establishment of high-level meteorological stations will be no longer delayed. It is true that none of the mountains in the United Kingdom are so high as in the other countries above enumerated where high-level stations have been and are about to be established. But on the other hand the British Isles occupy a position more important for meteorological purposes than almost any other European country, inasmuch as their westward position enables British meteorologists to obtain the earliest information regarding the great storms which sweep across the Atlantic, and of which warning as soon as possible should be given in Europe. Great Britain's duty, interest, and credit as a nation concur therefore in this matter; and it is hoped that measures will soon be taken to establish these high-level stations in the three divisions of the United Kingdom, unless, in fact, we are prepared to see the problems presented by the phenomena of the higher air worked out in other countries.

COAL

Coal: its History and Uses. By Professors Green, Miall, Thorpe, Rücker, and Marshall, of the Yorkshire College. Edited by Prof. Thorpe. (London: Macmillan and Co., 1878.)

I SHALL be much surprised if this composite little volume fails to attract the attention of many students of nature, but especially of such persons as are practically connected with coal, either as students, as proprietors, or as workers. The five professors of the Yorkshire College of Science who have combined to produce the volume are men thoroughly competent to deal with the portions of the subject which they have severally undertaken, and the result of their labours is a book at once picturesque and scientific.

Prof. Green commences the work by two chapters on the geology of coal. After dealing with the general phenomena of the deposition of sandstones, shales, and limestones, he proceeds to examine the special features of coal and the probable conditions attending its formation. In doing so he grapples with the peculiar questions connected with the well-known lamination of coal and the alternation of the brittle, lustrous, bituminous layers with those of the so-called mother-of-coal or mineral charcoal. This subject of course raises the question of the origin of these two elements—a question which still presents curious and unsolved difficulties. The mineral charcoal chiefly consists of cubical fragments of bark mingled with some vascular or woody elements of plant-stems. Prof. Green correctly points out that "the woody character of this mother of coal is palpable even to the unaided eye," further adding "that it is possible, in some cases, to say what the plant was of which they (*i.e.*, the fragments of charcoal) originally formed a part." I am afraid that this latter feat is not easily performed. The vascular tissues which we chiefly find in this mineral charcoal are not those seen in Lepidodendron and in Sigillaria. The absence of the latter structures is one of the facts not easily explained. The vessels forming the ligneous zones of these two representatives of the carboniferous flora are always of the barred or pendoscalariform type. The dominant element in the mineral charcoal consists of the various modifications of cellular tissue found in the bark of these, and many other unrecognisable, plants, but the vessels are mainly of the reticulated type. They closely resemble the vascular elements found in some Calamites, in most Asterophyllites and Sphenophylla, and in all the known Lyginodendra. Whether the barred vessels of the Lycopodeaceous plants did not form a part of the vegetable mass converted into coal, or whether, being there, they were bituminised more readily than others, is not easy to say. I am inclined to believe in the latter explanation; anyhow, I have as yet failed to find a solitary fragment of one of these *barred* vessels in the mineral charcoal. A fragment of American coal, sent to me many years ago by that distinguished microscopist, Dr. Bailey, of West Point, consisted wholly of numerous layers of similar reticulated vessels which had not undergone bituminous disintegration. The laminæ of mineral charcoal alternate with those of the more bituminised coal with great irregularity; in some specimens they are distributed in about equal quantities, in others thick bituminous layers separate the charcoal layers very widely. Whatever the agency may have been that brought about the result, this lamination shows that, in most instances, there have been irregularly recurring periods when innumerable, perfectly carbonised, but only partially disorganised, fragments of certain decaying stems were strewed over the surfaces of those portions of the vegetable mass which became converted into the more bituminous laminæ of the coal. In other cases I find no difficulty in seeing the charcoal intermingled with, and actually undergoing conversion into, the bituminous condition, whilst interposed layers of perfect macrospores have undergone no such conversion. The charcoal fragments are

precisely such as we see when an old post, or the stem of a dead tree, undergoing decay, is breaking up into small cubical or rectangular pieces, and which would float freely upon the surface of an overflowing current of water.

My present impression is that these charcoal layers have originated in the decay of aged stems, such as have produced the "pot-stones" and "pot-holes" common in our coal-mines. The wood and the greater portion of the bark would accumulate, in a fragmentary state, within the hollow cylinders of the less easily destroyed bast-layer of the bark of such stems, until some recurring flood converted the damp ground into a temporary shallow lake, filling all these cylinders with water, when all such fragments would speedily float out, leaving the empty cylinders to be occupied by the sands and clays by which they are almost always permanently filled. The displaced vegetable fragments would swim freely for a time, diffused widely over the surface of the waters, but, as the latter subsided, they would settle down upon the layers of more completely disorganised vegetable soil, which, being already damp and soddened, would be likely to remain undisturbed by the temporary and sluggish currents that would exist where a forest-covered swamp was thus overflowed.

Prof. Green appears to balance very fairly the respective measures in which reproductive spores and the merely vegetative portions of the Carboniferous plants have contributed their quota to the carbonaceous mass. At the same time, much more work remains to be done before our theories on this subject can be regarded as wholly satisfactory.

The chief point in Prof. Green's work which I should be disposed to criticise is his map representing the probable distribution of sea and land during the carboniferous age. We are so ignorant of the extent to which denudation has affected vast geographical areas, that all such attempts appear to be inevitably hypothetical. At the same time Prof. Green's reasonings on the subject are extremely plausible and ingenious.

The third chapter of the volume is devoted to the coal plants—especially to the two types of Calamites and Lepidodendron, with the near relative of the latter, the Sigillaria. Since this portion of the volume is avowedly based upon my own memoirs, criticism of any kind would be out of place here. I would only observe that Prof. Miall appears to have reproduced my notions, be they right or wrong, with great accuracy. I may, however, observe here that one of the points for which I have so long contended, in opposition to my French friends, viz., the close identity of Asterophyllites and Sphenophylla, has just received unanswerable confirmation. Herr von Stur *has obtained both these types of foliage upon one single plant*, the former being the ordinary vegetative foliage, and the latter the whorls of leaves belonging to the fruiting branches.

In the fourth chapter we find Prof. Miall upon his own ground. In it he deals with the animals of the coal-measures, to the history of many of which he has made such valuable contributions. The chapter affords a rich illustration of the progress which the animal palæontology of the coal-measures has made during the last half century. Within that period Dr. Hibbert first called attention to the large teeth and bones of the Burdie-house limestone. It was only in the third decade of the century that we began to find scanty fragments of similar objects in the Ardwick limestones of Manchester, and it was at a yet later period that the Wigan Cannel was found to be rich in remains of similar objects. How changed this portion of our knowledge now is the reader of Prof. Miall's interesting chapter will readily learn. Prof. Miall wisely explodes the baseless notion of an atmosphere ladened with a superabundance of carbonic acid—existing during the Carboniferous age—a notion which still reappears in some geological works, but which rests upon no probable foundation. On the other hand he very correctly shows the importance of studying the fishes of the Carboniferous rocks when attempting to classify these rocks by the light of their animal remains. He points out the rarity of the Carboniferous Ganoids in the mountain limestone contrasted with the comparative abundance of the Elasmobranchs—a statement which every geologist familiar with these rocks will readily confirm, and he shows also how difficult it is to determine between the several influences of marine and fresh-waters in producing the Carboniferous beds. At the same time, fully admitting the correctness of Prof. Miall's statement that the Ganoids become proportionately more numerous as we ascend from the limestone to the newer beds, the Elasmobranchs in the upper coals of Lancashire and Yorkshire are far more numerous than in any known estuarian or fresh-waters at the present day, and consequently they place a great difficulty in the way of our regarding the upper Carboniferous, sedimentary deposits as being absolutely due to fresh water. Prof. Miall admits that his conclusions on this point compel us to admit "the supposition that the Elasmobranchs were more largely fluviatile than in any other periods." On the other hand, seeing how largely the noble ganoids of the Permian, Liassic, and Cretaceous ages were undoubtedly marine, it may be as readily contended that the Carboniferous Ganoids were marine as that their Elasmobranch companions were fresh-water.

In the fifth and sixth chapters the chemistry of coal is dealt with. For this portion of the work I presume we are wholly indebted to Prof. Thorpe and his auxiliaries in his Leeds laboratory. This portion of the work is of high interest. Dr. Thorpe has made numerous new analyses, and amongst other matters he has endeavoured to throw further light upon the question first raised by Prof. Huxley, viz., the true influence of Lycopodeaceous spores in producing the bituminous portions of the coal. But though Prof. Thorpe's researches into this question are highly interesting, the problem is far from solved; hence I believe he proposes to carry out a further series of analyses, in the hope of throwing further light upon this obscure but important subject. Space does not admit of my referring to the numerous other chemical aspects of coal which Prof. Thorpe so carefully records.

The four remaining chapters deal respectively with coal as a source of warmth, a source of power, and with what is commonly called the coal question; in the *two* latter chapters, ground gone over by Prof. Jevons, some years ago, is again traversed by Prof. Marshall. To attempt to criticise these latter chapters would be presumptuous on my part, still I cannot quite accept Prof. Marshall's conclusions that what he calls "physical

waste" in contradistinction to "commercial waste," should be allowed to go on. If his argument is a sound one, a tenant is justified in only getting such coal as is *most* cheaply obtained, and in leaving buried in the bowels of the earth, unattainable by future generations, valuable material merely because the getting of it would involve more cost than would attend the raising of coal from thicker and more cheaply workable seams. When a tenant rents *all* the coals under a given acreage of ground his interest in the property is temporary and limited. It is therefore to his interest to raise only such coal as can be most cheaply raised in the shortest space of time. It is not necessary that the raising of the coal which he thus abandons should involve an actual loss to the tenant. It is enough for the argument that he would have to raise it at a diminished profit, which he will certainly not do if he is permitted to devote the same time and labour to such coal as will leave him more profit. Of course freedom of trade and labour suggest that a man should be allowed to pursue the course most profitable to himself, but seeing the vital importance of our coal supply to our existence as a manufacturing nation, it does appear to me that the coal-raiser should be prevented by the lord of the manor primarily—or, if he fails to do his duty, by the legislature—from thus wasting the chief instrument in the production of our national wealth—even if such interference involved some reduction of his profits, or of some addition to the price of coal.

I need not say more to show the interesting character of the contents of this unpretending volume. It is most creditable to its authors, and I shall be much surprised if its merits do not meet with a wide recognition.

W. C. WILLIAMSON

ASCENSION

Six Months in Ascension; an Unscientific Account of a Scientific Expedition. By Mrs. Gill. (London: John Murray, 1878.)

THOSE who know anything of Ascension will wonder how on earth any one could find sufficient material during even a six months' stay to write a volume of 300 pages upon it. We doubt if any one but a lady circumstanced as Mrs. Gill was could have made a readable story out of the barren materials to be found on this land-ship of an island, as it really is, to all intents and purposes; and she has managed to write a thoroughly interesting narrative. If every scientific worker were as fortunate as Mr. Gill in having so sympathetic a companion and coadjutor to tell all the circumstances of his work, the world might think a great deal more of those apparently dry figures and easily-expressed results, which seem to have no touch of nature about them. To those who see only the scientific side of the matter, it may seem a very simple and very pleasant thing to watch the stars night after night; let such read Mrs. Gill's book, and perhaps they will have more sympathy and perhaps a little pity for astronomers sent on scientific expeditions to remote islands.

Mr. Gill, as many of our readers will remember, spent the last six months of 1877 on the Island of Ascension for the purpose of observing Mars in opposition, an opportunity occurring then such as would not occur again during the century. Lord Lindsay lent his celebrated heliometer, the Astronomical Society granted 500*l.*, and the Admiralty did all in their power to make Mr. Gill's sojourn on Ascension as pleasant and successful as possible. In an introductory chapter Mr. Gill gives an exceedingly interesting sketch of the principal previous attempts which have been made to measure the distance of the sun, and the results that have been come to with regard to that hitherto rather inconstant "constant." The perusal of this chapter will not only be instructive to the general reader, but must greatly increase the interest of the subsequent narrative, showing as it does the important results that depended on the success of the expedition, the human side of which is so graphically described by Mrs. Gill. She herself gives a brief but very successful explanation, in popular language, of how the sun's distance is measured.

As outgoing vessels seldom touch at Ascension, the expedition, consisting of Mr. and Mrs. Gill, with their heavy baggage, were detained for some time at St. Helena, a detention which both seem to have enjoyed. Mr. Gill succeeded in finding what he, with considerable probability, surmises to have been the site of the observatory used by Halley, in 1677, to observe the transit of Mercury, and make his catalogue of southern stars. They of course saw all the lions of the island, and Mrs. Gill's descriptions are so clear and fresh that even those who have read much about St. Helena will find in them much to interest. Even when Ascension was reached, it was no easy matter to land through the great "rollers" which are so characteristic a feature of some Atlantic islands. We hear a good deal about these puzzling phenomena, which are so difficult to account for, but which Mrs. Gill is inclined to think are probably due to the cause suggested by Capt. Evans. That keen-sighted hydrographer thinks these rollers are probably the far-reaching result of the breaking-up of the continents of ice in the Antarctic regions, miles and miles of which break off, and, plunging into the sea, give rise to huge submarine waves, whose strength is not expended even when they reach Ascension and St. Helena. Mrs. Gill's description of life in Ascension, and especially of the life of the "expedition," is given with a good-natured and graphic pencil. At first the observatory was established on an admirable piece of ground at George Town (or "Garrison," as it is called on the island), on the West Coast, where a very nice cottage was allotted to the astronomer and his wife. Her housekeeping difficulties are amusing enough to read of, though at first awkward enough to one unaccustomed to garrison or rather naval life. Ascension is to all intents and purposes one of her Majesty's ships at anchor, and everything is conducted exactly as on shipboard. All food and drink are served out at fixed time as rations, and as supplies are at all times limited, there is ample room for economical management, and little room for luxury and extravagance. The new-comers soon became accustomed to the routine of the land-ship, and after a day or two got comfortably settled in their cottage, and had the heliometer and other instruments most satisfactorily located on their solid asphalte floor. But, unfortunately, this happy state of things was not without a cloud—a real genuine cloud—which threatened to frustrate the great object of the voyage and all the preparations. This

cloud persistently hung over the island and prevented anything like satisfactory observation, and had it not been for Mrs. Gill's pluck, failure might have been the result. It occurred both to her and her husband that the cloud was only local, and to prove the truth of this suggestion, Mrs. Gill undertook a journey along the coast, starting about midnight, over great cinders and deep rifts, to a point almost four miles south. The supposition proved true, and amid many difficulties the observatory was dismounted, and the instruments removed to the south-west of the island, to a small inlet christened Mars Bay, in memory of the expedition. But what a change from "Commodore's Cottage," as the "Garrison" residence was called. Ascension is an extinct volcano, and it is now little more than a huge mound of cinders and dust. On such floor did Mr. Gill pitch his tent, and on such a base had he to erect his delicate instruments. The discomforts attending his surroundings knocked him completely up, but with the help of Mrs. Gill and the doctor he was set on his feet again, and by the ministry and companionship of the former the encampment was made tolerable. Fortunately after all these hardships and trials and doubts as to weather, the observations at the critical time were completely successful, as were a long series of subsequent comparison observations. The captain of the island and his subordinate officers deserve the greatest credit for the assistance and support which they gave to the enthusiastic astronomer and his ever-helpful and cheerful wife. After the real work of the expedition was completed Mr. and Mrs. Gill made several excursions over the tiny island, and with the exception of an oasis on the summit of the "mountain," the island seems dreary in the extreme, and Mrs. Gill failed to find the neat square gardens and paved streets seen by Sir Wyville Thomson. Altogether, on a very unpromising subject, she has succeeded in writing a really interesting and instructive book, telling us much about the islet and its inhabitants, and still more about the circumstances under which an important piece of scientific work was done. We strongly recommend it to the perusal of our readers.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Schwendler's Testing Instructions for Telegraph Lines

In the absence of my friend Mr. Schwendler in India, perhaps I may be allowed to offer a few remarks on the notice of his book on line-testing which appeared in NATURE, vol. xix. p. 192.

It must be remembered that the book is primarily intended for the use of the officers of the Indian Telegraph Department, and that the conditions in that country differ very much from those in England. Here the overland lines are in such positions that any accident happening to them may be easily detected, but in India the lines run in many parts through countries with few inhabitants, and the distances between stations is sometimes very great. Formerly when a breakdown or fault occurred, the line-riders were sent out from the stations to find out what was the matter, and Mr. Schwendler gave a very amusing account of two of these natives riding out from the two ends of the line to find a fault, meeting in the middle, salaaming and asking one another if anything wrong had been seen. On receiving a negative reply they salaamed and rode back, but the line was none the better for it. It must be, to say the least, tedious to ride many miles over a rough country staring at a wire on an Indian sky on the chance of finding a dead snake across the wires or a bird's nest on an insulator. These difficulties suggested the very systematic line-testing now in vogue in India.

It is unfortunate that the reviewer has shown such a disrespect for mathematical formulæ. There is no doubt that the book swarms with them, but it is by means of these that Mr. Schwendler has discovered many of the facts stated in the book, some of which your contributor seems to doubt. I will, with your permission, instance two cases. He writes, "Indeed it is very doubtful whether his proof that the sensibility of the bridge method is greatest when the branch and the resistance are equal is true. At any rate in our practice we find that the more delicate the galvanometer of the bridge the more sensitive and the more accurate is our test."

In the last sentence it is not quite clear what the reviewer means by a "delicate" galvanometer. I do not know that Mr. Schwendler says that the galvanometer should not be delicate, but he does say that its resistance should bear a certain relation to the resistance measured. For a high resistance a galvanometer of high resistance should be used, and for a low resistance one of a proportionately low resistance. But the alteration of the resistance should not be made by using only a portion of the coils. This is fully explained on p. 22, where it is shown that the coils should be connected either consecutively or parallel in order to increase or diminish the resistance of the instrument. Thus all the convolutions of the galvanometer are used, but as the resistance is diminished in the second case a larger flow of electricity takes place and a greater deflection is produced. The results of these theoretical considerations are so readily tested by experiment that it is surprising that the author of the notice should have thrown doubt on their accuracy. I have therefore thought that it might be useful to make some measurements which have fully confirmed the theory. I will not trouble you with all the experimental numbers of about 160 measurements, which would be as "appalling" to the readers of NATURE as Mr. Schwendler's formulæ are to the writer of the review. A reflecting galvanometer with two coils was used. Connected consecutively their resistance was 5590 units and parallel 1405. The results would have been more striking if the coils had been of unequal resistance so that the parallel resistance would have been less, or if the two halves of the bobbins could have been connected parallel, which would have reduced the resistance to about 700 units. The following table will show the results obtained on measuring three resistances with varying branch resistances, and with the two arrangements of the galvanometer the deflections of which were noted when a certain alteration of the comparison coil was made:—

Resistance tested. Units.	No. of cells used.	Resistance of branches. Units.	Alteration of comparison coil. Units.	Deflection of spot of light with galvanometer coils: Consecutive.	Parallel.
4740	20	10	20	14	15
—	—	100	—	91	95
—	—	1000	—	192	190
760	20	10	4	23	39
—	—	100	—	140	234
—	—	1000	—	333	386
90	1	10	2	47	93
—	—	100	—	77	148
—	—	1000	—	77	121

These numbers show that the branches should approximate to the resistance measured and also that the galvanometer resistance should be smaller when a small resistance is measured. Calculation shows that the most advantageous resistances of the galvanometer in the three cases would be 2870, 880, and 95 respectively.

There is another point with regard to testing with Wheatstone's Bridge, which is not noticed in the review, but to which I may be allowed to direct attention;—that is, the position of the galvanometer. It is not indifferent in which diagonal of the bridge the battery and galvanometer are placed when the branches are unequal. In such a case the method is much more delicate when the galvanometer is placed in the diagonal joining the junction of the two largest resistances with the junction of the two smallest. As, I believe, we have in this laboratory the only Wheatstone's bridge yet constructed after Mr. Schwendler's design, by which the position of the galvanometer and battery can be altered by the shifting of four plugs, I have made a few tests which will show the advantage of this arrangement.

The diagonal joining the junction of the branches with the junction of the comparison coil and the resistance measured is called *m n*; the other diagonal being *p q*.

Resistance measured. Units.	No. of cells used.	Resistance of branches. Units.	Alteration of comparison coil. Units.	Deflection of galvanometer in diagonal *m n*	Deflection of galvanometer in diagonal *p q*
		$\frac{b}{a}$			
90	1	$\frac{100}{100}$	2	148	147
—	—	$\frac{100}{1000}$	20	53	122
—	—	$\frac{10}{1000}$	200	$7\frac{1}{2}$	$34\frac{1}{2}$

It will thus be seen that when the branch resistances are equal it is indifferent in which diagonals the galvanometer and battery are placed; but this is not the case when branch *a* is greater than branch *b*. It is hardly necessary to observe that in a practical test more than one cell would be used when the branches are unequal, in order to obtain much larger deflections, and more accurate measurements. The Unseen Universe—Paradoxical Philosophy

THE principle of continuity forbids us to imagine that the collocation called the atom has existed as it is from all eternity. This the authors of the "Unseen Universe" have insisted upon, and I need not go further than their title-page to remind Mr. Hallowes that in like manner they do not contemplate a future eternal existence for the atom.

But this principle cannot tell us what was the exact nature of the thinkable antecedent of the present universe, nor can it tell us the exact nature of that state which will follow the disappearance of the present system. There are, however *strong scientific analogies* which lead us to believe that the thinkable antecedent of the present system was a spiritual unseen, which not only developed but which now sustains the present order.

Is it therefore necessary that I myself should in like manner help to sustain some inferior universe? I repudiate any such obligation. I am not fit for it.

Because a little boy has a father, is it logically essential that he should likewise have a son?

HERMANN STOFFKRAFT

Schloss Ehrenberg, Baden, January 11

Molecular Vibrations

IN NATURE, vol. xix. p. 158, col. 2, is the following:—

"It has been suggested that the same molecule may be capable of vibrating in different ways, and thus of yielding different spectra, *just as a bell may give out different notes when struck in different ways*." It is well to note that the bell as a whole gives but one sound, and the other sounds are not true harmonics, but come from parts of the bell, either before the whole is in vibration or from parts badly amalgamated, flaws in the metal, air-bubbles in pouring into the mould, lack of homogeneity, inequalities in the mould, &c.

The noises in a belfry are most discordant, whereas harmonics form a succession of consonances—octave, fifth, fourth, major and minor thirds, seventh and treble octave.

WM. CHAPPELL

The Electric Light

WHILE so many experiments are being made on lighting by the incandescence of infusible materials produced by electric currents, it is well to point out that Dr. Draper, as early as 1844, used a strip of platinum so heated to determine the facts that all solid substances become incandescent at 977° F., that light increases in refrangibility and intensity, and that the order of the colours emitted followed the true prismatic order as the temperature increases.

Dr. Draper says: "Among writers on optics it has been a desideratum to obtain an artificial light of standard brilliancy. The preceding experiments furnish an easy means of supplying that want, and give us what might be termed a 'unit lamp.' A surface of platinum of standard dimensions raised to a standard temperature by a voltaic current will always emit a constant light. A strip of that metal one inch long and $\frac{1}{20}$th of an inch wide, connected with a lever by which its expansion might be measured, would yield at 2,000° a light suitable for most purposes. Moreover, it would be very easy to form from it a photometer by screening portions of the shining surface. An ingenious artist would have very little difficulty, by taking advantage of the movements of the lever, in making a self-acting apparatus in which the platinum should be maintained at a uniform temperature, notwithstanding any change taking place in the voltaic current." (*Vide* Draper's "Scientific Memoirs," p. 45.)

Wimbledon, January 11 W. H. PREECE

Force and Energy [1]

III.

IN consequence of energy not being a directed quantity we come at once upon an important distinction between transference of energy and transference of momentum. There may be a large force exerted, *i.e.*, a large amount of momentum rapidly transferred, without there being any accompanying transference of energy. In the distance V on the two sides of a given section of the stressed material through which the two opposite streams are flowing, there is lodged a certain amount of motion which is the same in the one portion on the one side of the section as in that on the other side. The momentum and the energy lodged in each portion are simply different functions of one and the same motion. In unit time the whole of the motion in the portion on the one side of the section is transferred into the portion on the other side, and *vice versâ*. The resulting quantitative transference of the one function of the motion is double what would take place if only one, instead of two, opposite streams were flowing through the section, the reason being that this function is a directed quantity. The resulting quantitative flow of the other function of the motion is zero, because it is a function which has no direction. The rate of transference of momentum, or the force, is in this case eE, the sign being given by the sign of e. Suppose, now, one only of these streams of motion to be flowing past the section, the rate of transference of momentum being $\frac{1}{2}eE$, where e is the geometrical ratio of extension, or the strain. The rate of transference of energy remains to be calculated. The material may be either at rest or in motion. In fact whether it is to be considered at rest, or at what velocity it is to be considered moving, depends altogether upon the set of bodies relatively to which the motion is to be measured. Its relative velocity may also be either uniform or variable. The relative velocity of the centre of inertia of the material lying between two given sections will be uniform if the whole of the motion measured in any quantitative way flowing in through one of these sections is equal to that simultaneously flowing out at the other.

Suppose that before the force begins to act there is a uniform velocity, v_0, throughout a given length. As soon as there is a uniform force, $\frac{1}{2}eE$, throughout this whole length, the flow being only in one direction, one half the particles will have at any instant the velocity, v_0, while the other half has the velocity $(v_0 + v)$, where $v = e\sqrt{\frac{E}{\mu}}$.

$V = \sqrt{\frac{E}{\mu}}$ being the velocity of stream-flow; there is in the length V lodged an amount of momentum $(V\mu v_0 + \frac{1}{2}V\mu v)$ for unit section throughout that length. Of this amount $\frac{1}{2}V\mu v = \frac{1}{2}eE$ is transmitted forwards per unit of time. The mean velocity of the material is also $(v_0 + \frac{1}{2}v)$.

[1] Continued from p. 219

The amount of kinetic energy lodged in this length measured relatively to the same set of bodies as v_0 relates to, is

$$\left\{\tfrac{1}{2} \cdot \tfrac{1}{2} V\mu \cdot v_0^2 + \tfrac{1}{2} \cdot \tfrac{1}{2} V\mu \cdot (v_0 + v)^2\right\},$$

of which there is transmitted forwards per unit of time the amount

$$\tfrac{1}{2} \cdot \tfrac{1}{2} V\mu\left\{(v_0 + v)^2 - v_0^2\right\} = \tfrac{1}{2} V\mu v\left\{v_0 + \tfrac{1}{2}v\right\} = \tfrac{1}{2} eE\left\{v_0 + \tfrac{1}{2}v\right\}.$$

This is equal to the force multiplied by the mean velocity of the material. The truth of this last proposition is quite independent of which group of bodies the velocities are measured relatively to. The energy transferred is to be measured relatively to the same group as that to which the mean velocity of the material is measured. But the expression for the rate of transference of energy consists of two parts, only one of which varies with the choice of axes of velocity-measurement. Thus the acting-force $= \frac{1}{2} eE =$ rate of transference of momentum; the mean velocity of the material $= v_0 + \frac{1}{2} e \sqrt{\frac{E}{\mu}}$; and the rate of transference of energy $= \frac{1}{2} eE \left\{ v_0 + \frac{1}{2} e \sqrt{\frac{E}{\mu}} \right\} =$ rate of doing work. The sign of the last rate indicates simply in which direction energy is flowing. The sign depends on that of the mean velocity and on that of e. Here e is a linear strain, and must have the sign $+$ or $-$. If it is a twist it should have the sign $\sqrt{-1}$ or $-\sqrt{-1}$.

The constant part of the energy transferred—that part independent of the axis of reference—is $\frac{1}{4} e^2 E \sqrt{\frac{E}{\mu}}$. This and the amount of the acting force cannot be altered in any way by varying the choice of axes. This result at first sight seems somewhat contradictory to the notion that energy is a thing of infinitely greater objective reality than force is. The amount of the momentum of a body's visible motion and the amount of its energy can be made just as great or as small as we please, by simply imagining one or other group of bodies to be at rest. In this way its momentum may be made to vary at will from $-$ infinity to $+$ infinity, while its energy may be made to vary from zero to $+$ infinity. Etymologically the words "force," "momentum," and "energy" are mere names, but the first, force, has objective reality in the sense that it is related only to the fundamental units of mass, space, and time, and does not depend at all upon an arbitrary choice of axes; while the second and third, momentum and energy, are simply products of the imagination.

The first of these statements, viz., that respecting the physical reality of force in the sense above explained, may be objected to because of the appearance of velocities in the expression for it $\frac{1}{2} eE = \frac{1}{2} V\mu v$. But here the first velocity $- V$ is the length of material passed through by a wave of longitudinal momentum in unit time, and it is an experimental fact that this is quite independent of the velocity of the material measured relatively to no matter what set of axes. The second velocity v is double the mean velocity of the material after the force has begun to act, measured relatively to a set of axes, relatively to which the material was at rest before the force began to act. Thus, v may be looked upon as containing in itself the definition of the axes relatively to which it is to be measured, and thus its magnitude is not at all at the disposal of our imagination.

Similarly the rate of transference of energy measured relatively to a set of axes with respect to which the material was at rest before the energy began to be transferred, is absolute in the sense that we cannot arbitrarily alter its magnitude by an exercise of the imagination.

We have in the above supposed a single stream of motion flowing continuously onwards and through the material under consideration, so that that material neither gained nor lost on the whole momentum or energy. If the portion of material considered does not pass on the whole motion it receives, but retains either a part or the whole of it, its rate of gain of energy is to be found by applying the above equations to its one or two or more surfaces, or surface layers, through which transfers of energy are going on. If it is receiving energy only through one surface and losing it through no surface, its rate of gain of energy is $\frac{1}{2} e\mathrm{E}\left\{v_0 + \frac{1}{2} v\right\}$, where e is the strain at the receiving surface, and $(v_0 + \frac{1}{2} v)$ the velocity of that surface, measured in the proper directions. It is to be observed that new finite increments of velocity gradually spread over the whole material, so that each small part is accelerated by fits and starts, and the whole mass is accelerated by what might be called pulsations, or, in the case of the strains being shearing ones, in a sort of wriggling fashion. The surface particles have at any instant the velocity v_0, say. They instantaneously gain the velocity v and immediately afterwards lose it again, and experience this change a great many times for an interval during which their time-average velocity is $(v_0 + \frac{1}{2} v)$. After this interval they for another equally long interval alternate between the velocities $(v_0 + v)$ and $(v_0 + 2v)$ in such a way that their time average velocity is $(v_0 + 1\frac{1}{2} v)$.

The gain of energy in one unit of time is in magnitude evidently dependent on v_0: that is, on the axes of reference arbitrarily chosen. Thus, not only can we alter the magnitude of the energy resident in a body arbitrarily by choosing different sets of axes, but, by a simple exercise of the imagination, we can set the energy possessed by any portion of the universe increasing at any arbitrarily desired time-rate. The momentum may be imagined what we like, but we cannot exercise our imagination upon its rate of transference, or force; on the other hand, both the amount at any time and the rate of transference of energy we may make what we please. This last, however, does not at all invalidate the conservation of energy as a proposition concerning the energy measured relatively to a given set of axes; because, although the time-rate of gain of energy of one portion of the collection of bodies investigated may be increased by changing from one set of axes to another, still that change creates simultaneously a correspondingly increased rate of loss of energy in another part, namely, that other part from which the energy is being transferred to the former.

It is to be observed that this change arbitrarily accomplished in the magnitude of rate of exchange of energy is only possible if a force is acting. If no force is acting, e is zero, and the rate of exchange of energy is zero, whatever v_0 be.

This mathematical possibility of altering, by a change of motion-axes, the time-rate of gain of energy of any special portion of the system, seems to me to furnish the strongest conceivable argument in favour of there being existent no other kind of energy except that of motion, *i.e.*, kinetic energy, represented algebraically by the formula $\frac{1}{2}\mathrm{MV}^2$. If the conservation of energy is true in any sense which will include kinetic energy as part of the energy which is conserved, and if the rate of transference of energy from one part of the system to another can be altered by arbitrary changes of the velocities effected by choosing different axes, then there can be no energy that is not energy of relative velocity.

Comparing the kinds of reality to be ascribed to "force and to "energy," we see that while force has quantitative definiteness quite independent of the stand-point arbitrarily assumed by the physical imagination in viewing them, it lacks that kind of reality which some believe to be an attribute of those things only which are "conserved," because force comes into existence and goes out of it again. This kind of reality may be more or less aptly illustrated by supposing that the personality of a human being be not immortal but to come into existence either gradually or suddenly with the birth of the human being, and to go out of existence with its death. If this were the case, and if the results of the temporary existence of this human being were always to live in the subsequent history of human phenomena, then force would have very much the same sort of reality as the personality of a human being. On the other hand, the quantity of energy that exists depends on this standpoint of the imagination, but so long as this standpoint is unchanged there is no change in the amount of the energy. In other words it is "conserved." So long as the position from which it is viewed is not shifted energy can neither be created nor destroyed. To make for energy an illustration somewhat parallel to the above made for force, suppose that all mankind had agreed upon a certain unit of goodness, and that the Deity was a thing the amount of whose goodness, measured by this unit, was really dependent upon the characters of the philosophies believed in by different sets of men, or upon the characters of the men themselves, then the beneficence of the Deity would be constant so long as the philosophic stand-point from which he was considered remained the same, and would have no other kind of constancy. If this were the case then energy would have very much the same kind of reality as the Deity. Again, momentum is conserved in the same way as energy. Also, force being the rate of transference of momentum, the real existence of force implies also the real existence of motion, of which energy is

simply one of various possible algebraic function; that is, of which energy is one of various possible quantitative measures, and of which momentum is another such measure. But although the reality of force implies the reality of energy and of momentum, the absolute quantitative definitiveness of force does not imply any corresponding quantitative definiteness of energy or of momentum. Now physics is distinguished from metaphysics by being essentially quantitative. It appears, then, that force is a physical reality independent of relation to axes of reference, and that energy and momentum become physical realities only when they are referred to such axes, because when not so referred, they have no quantitative definiteness. They remain, however, when not referred to axes, what may be called non-quantitative realities, and probably many people would choose to call them on that account metaphysical realities.

In conclusion I may offer one remark not strictly bearing upon the subject of this letter, which is the proper PHYSICAL use of the words force and energy, but which was suggested during an explanation of the above definition of force to a friend. There are some minds so constituted that they cannot get on at all without continually referring to metaphysical ideas. This fact should make those whose minds are not so constituted unwilling to believe, as they are very apt to do, that metaphysics is only an unreal, improper, and injurious phantasy or disease of the brain. If there are two such real sciences as metaphysics and physics, in the first place it is clearly advantageous to avoid confusion of the two as far as possible, and we may hope to be able keep them separate from the top down to the base where they rest together, or one upon the other. If there are certain words which it is very convenient to use in both these sciences and with accuracy, it is clear that they must have different definitions, *i.e.*, different meanings in the two. But it would be unfortunate if there were no correspondence between the two meanings. If the two sciences are realities they must consist in two different methods of assimilating as part of our knowledge the same facts; and the statements of the one science ought to be capable of definite translation into the language of the other. And this ought to be held in view in arranging the nomenclature of the two. Now I think that the strictly physical definition of force I have given, viz., the time-rate of transference of momentum, has a true correspondence with the ordinarily accepted metaphysical idea of force as "the cause of the change of velocity in masses." Metaphysically the cause of the acceleration of momentum of the one body is the transference of momentum from the other body, and this transference is also the cause of the retardation of momentum of the other. In the physical definition quantitative accuracy is obtained by introducing the idea of the "time-rate." In a metaphysical definition quantitative accuracy is neither possible nor is it desired, the inherent difference between metaphysics and physics being that the latter is quantitative while the former is not so. The friend to whom I threw out this hint objected that I was here only going one step further back, and that the question became "what was the cause of the transference of momentum?" It was evidently he who had made the step backwards, and of course it was a metaphysical step, not objectionable in itself, but having no bearing on the matter in hand. The above question is no objection to the metaphysical statement or definition, that the cause of the acceleration of momentum is the transference of momentum. If metaphysics is fit to do anything at all it ought to be able to investigate the cause of a cause; but even if it were not able to follow the chain of causes beyond any certain point, that would not constitute any objection to the statements of causative sequence made in following along the chain to the possible limit. The metaphysical answer to the question, "What is the cause of transference of momentum?" would probably be different according to the circumstances of the transference, whether it were by impact or by gravitation, or otherwise. To show, however, that my physical definition of force has a true correspondence to the metaphysical idea, it is quite unnecessary to answer this question, it is unnecessary to go beyond the cause which is called "force" in metaphysics.

ROBERT H. SMITH

Absorption of Water by the Leaves of Plants

I FEEL sure that many of your practical readers will be pleased with the article in NATURE, vol. xix. p. 183, on the "Absorption of Water by the Leaves of Plants," as a correction of a fallacy long held by many physiological botanists in antagonism to the experience of plain observers of nature.

In reference to the concluding remark on the statements of Prof. Calderon, the following may perhaps be interesting.

Every botanist who visits my Sewage Farm is struck with the luxuriance not only of the cultivated crops, but with that of weeds found growing, out of reach of the hoe, on hedge-banks and places whence it is impossible for their roots to reach the fertilising stream, which readily accounts for the growth of the crops.

It seems clear, therefore, that plants can absorb nitrogenous organic matter which may be wafted over their leaves by winds from a sewage-irrigated field, and I welcomed Mr. Darwin's account of insectivorous plants as a confirmation of my theory; but, after all, no one has ever doubted the power of absorbing carbon through leaves since van Helmont's celebrated experiment with the willow, and it can hardly be unnatural to credit plant-life with the power of obtaining another element of nutrition by the same channel.

ALFRED S. JONES

Havod-y-wern Farm, Wrexham

The Formation of Mountains

I HAVE deferred replying to Mr. Fisher's letter (NATURE, vol. xix. p. 172) till I had an opportunity of looking at Maxwell's "Theory of Heat;" but, having done so, I am no wiser, for I do not find the point in dispute anywhere referred to. In the "English Cyclopædia," art. "Heat," I find, however, the following statement: "If we suppose the mass of the earth to have been at any remote period at a very high temperature, the effect of the radiation of its heat through the colder surrounding space would be, to cool first the superficial strata, and successively, *though in a less degree*, the internal strata." This slower cooling of the internal parts of a heated mass seems a necessary result of the "law of exchanges," to which the supposed "more rapid cooling of the interior of the globe than the crust" seems as decidedly opposed.

Mr. Fisher's illustration certainly shows how the centre *might* cool more rapidly than the outside, if heat were not subject to laws, and could set the law of exchanges at defiance. He says: "As the people disperse they move off the more quickly the further they get from the dense mass." This would be true for heat, and exactly corresponds to the quotation given above from the "English Cyclopædia;" but it is inconsistent with Mr. Fisher's statement a little further on, that the numbers in an outer belt "may continue about the same, while those in the central crowd become fewer and fewer." The two things are contradictory; and I still fail to see how the "more rapid cooling of the interior of the earth," limited as it must be to that superficial layer within which the effects of solar heat are confined, can be held to furnish a *vera causa* for the compression and contortion of deeply seated rocks and their upheaval into mountain chains.

ALFRED R. WALLACE

Musical Notes from Outflow of Water

EVERY one is familiar with the sounds produced by water running out through a pipe from the bottom of a vessel, when the water-level has got low. The other evening I witnessed a phenomenon of this order, which has, I think, certain interesting features. Desiring to empty my cistern, and the pipes being frozen, I rigged up a gutta-percha tube siphonwise, and brought the water through it. When the orifice of the tube in the cistern got partially uncovered by the descending water-level, a series of rhythmical vibrations was generated, giving a musical note. The plane of the orifice was about vertical; but notes may be had when it is at any inclination with the horizontal water-surface. The intensity of the notes depends, I believe, partly on the difference of level of the vessels; but I cannot furnish exact data as to this, or the way the pitch is affected by various influences (width of pipe, &c.). Would some one proffer an explanation of the "mechanism" or essential character of the phenomenon?

M.

Shakespeare's Colour-Names

MR. BREWIN's assertion that Shakespeare's "word was doubtless *keen*" (not *green*) in the passage ("so green, so quick, so fair an eye") in "Romeo and Juliet," iii. 5, may be put on a par with his "wonder that the correction was not made long

ago." That alteration was made by Sir Thomas Hanmer, and has been rejected by every subsequent editor, and rightly so. "Green" was a common epithet for the eyes, and examples occur in many of our early poets, from Chaucer to Milton. Dyce quotes from H. Weber (*à propos* of Cervantes), "Green eyes were considered as peculiarly beautiful." We have of Neptune, "Thy rare green eye," in "The Two Noble Kinsmen," v. 1, in a passage attributed by some to Shakespeare. That Shakespeare wrote *green* in "Romeo and Juliet" I think beyond reasonable doubt; and if he wrote *green* he certainly meant *green*, and not *blue:* for in "A Midsummer Night's Dream" green eyes are compared to leeks. In our day violet eyes have the precedence over green eyes, yet I think there is still a kind of fascination in the latter. I leave the eagles to the naturalists. *Ne sutor, &c.*

C. M. INGLEBY

Valentines, Ilford

OUR ASTRONOMICAL COLUMN

A VARIABLE STAR OBSERVED BY SCHEINER IN 1612.—In the last number of the "Vierteljahrsschrift der astronomischen Gesellschaft," Prof. Winnecke examines an observation made by Scheiner, of *Rosa Ursina* notoriety, which appears to involve for its explanation the variability of a star at a past time which of late years has exhibited no fluctuation in brightness. In Scheiner's second work, "De Maculis Solaribus," published at Augsburg in 1612, are several letters addressed to his patron, Welser, one of which, dated April 14, 1612, contains observations of Jupiter and his satellites from March 29 to April 8. (It will be remembered that Scheiner regarded the solar spots as in reality solar satellites, which explains the introduction of notices of the satellites of Jupiter in a work professedly relating to sun-spots.) On March 30 he remarked, in addition to the four known satellites of the planet, a fifth star in the same field of view, not observed on the preceding night. This star diminished to invisibility on April 9. Suspecting a slight proper motion, it was regarded by Scheiner as a *fifth satellite* of Jupiter. From figures showing the position of the star with respect to the planet on March 30 and April 7, it may be inferred that they were in conjunction in longitude on the latter day, with a difference of latitude of 10′, the star to the south. Some years since Prof. Winnecke had calculated the place of Jupiter from Bouvard's table for the date of observation, with the view to identify the star which so soon disappeared, but Leverrier's tables for this planet being now available, he engaged Herr Küstner, one of the students at Strasburg, to compute the position of Jupiter for April 7, 1612, at Paris midnight: the geocentric longitude was found to be 136° 13′ 4″·3, and the latitude + 1° 6′ 52″·7 (differing about 6′ from Bouvard's place); hence the position of Scheiner's star, referred to the epoch of the "Durchmusterung"—1855·0, will be in R.A. 9h. 29m. 21·2s., Decl. + 15° 52′·1, thus identifying the object with a star of 8·5m., which the "Durchmusterung" places in R.A. 9h. 29m. 21·4s., Decl. + 15° 53′·5. There are several observations of this star; it occurs in Lalande's zone, 1796, April 4 (No. 18886 of the reduced catalogue), as 8m.; Bessel observed it twice in 1825, estimating it, on February 24, 8m., and on March 12, 7·8m., and Struve using it as a reference-star for Biela's comet on October 26 in the following year, also rated it 7·8m. Again, it was observed by Preuss with the Dorpat meridian circle, in March, 1833, and noted of the same magnitude, so that during this period its brightness appears to have been constant, and Prof. Winnecke adds that repeated comparisons made by himself during the last seventeen years have not indicated any variation. The close agreement of place identifies the star satisfactorily, and he infers that we have here an instance of a star which, though apparently constant during the present century, was variable in Scheiner's time. Prof. Winnecke remarks upon the interest that would attach to a spectroscopic examination of this object by the possessors of powerful telescopes. Its position for 1880·0 is in R.A. 9h. 30m. 44s., N.P.D. 74° 12′·7. He considers that, notwithstanding Scheiner's inexpressible prolixity, the author of the *Rosa Ursina* does not deserve the severe reproach which he has received at the hands of the astronomical historian, but that he was thoroughly candid in communicating what he had seen, and much acquaintance with his writings has strengthened this opinion.

The unusual phenomenon to which we have adverted appears to have made a strong impression upon Scheiner. who transmitted his observation on the instant to Welser,

THE ZODIACAL LIGHT.—We have already alluded in this column to the very questionable accuracy of a statement so often made in popular astronomical works, that the evening zodiacal light is best seen in these latitudes in March, near the vernal equinox, the inclination of its axis to the horizon being then greater than earlier in the year. Notwithstanding this circumstance, it appears certain that of late years the finest views, or we would say the most conspicuous exhibitions of the zodiacal light have occurred between the middle of January and the middle of February. Many instances of bright displays of the phenomenon during this interval might be mentioned. Thus, on February 6, 1856, Secchi records that the light at Rome was brighter than he ever remembered to have seen it, and of great extent; it was yellowish towards the axis, and while the more conspicuous part of the Via Lactea, in Cygnus, was invisible in a hazy sky at a low altitude, the light was traceable to the horizon; it was slightly curved towards the north, and is described as presenting on the whole "un grande spettacolo;" on this evening, it is added, the rest of the sky was illuminated in an unusual manner. Again, it was in the middle of February, 1866, that Mr. Lassell, during his last residence at Malta, witnessed a remarkable display. He says as he went up to the Observatory the striking brightness of the zodiacal light riveted his attention as never before. It was at least twice as bright as the brightest part of the Milky Way, and fully twice as bright as he ever saw it before, and Mr. Lassell upon this occasion also remarked that its character was quite different to that of the Milky Way, a difference more easily recognised than described; generally it is of a much redder hue. In 1874, in the neighbourhood of London, the most conspicuous displays took place on the evenings of January 14 and 17, and February 18, and in 1875, on January 24, 25, and 30, on the first of these evenings the zodiacal light was surprisingly conspicuous, decidedly reddish, and much excelling any part of the Milky Way. Observations on the position of the apex during these favourable views of late years fully support the conclusion of Prof. Julius Schmidt in his treatise on the phenomenon, published in 1856, that the maximum eastern elongation of the apex falls about the middle of January. Towards the end of March, on the contrary, there is a minimum, according to the Athens astronomer, as regards elongation, breadth, and the inclination of the axis of the light on the north side of the ecliptic.

BIOLOGICAL NOTES

NEW ASIATIC FISHES.—In the *Annals of Natural History* for 1873[1] was given a translation of Prof. Kessler's description of the new sturgeon, *Scaphirhynchus fedtschenkoi*, recently discovered in the Syr Daria or Jaxartes, and a note by Dr. Günther, pointing out the interest attaching to the existence in Northern Asia of a second species of this curious form, hitherto only known from the single species, *S. cataphractus*, of the Mississippi. Recently, however, a second Asiatic species of *Sca-*

[1] "On a Remarkable Fish of the Family of Sturgeons," &c. (*Ann. Nat. Hist.*, ser. 4, vol. xii. p. 269).

phirhynchus has been discovered in the Amou Daria or Oxus by Modest Bogdanoff, and named after the well-known governor of Turkestan, *S. kaufmanni.* This new fish was first described and figured in a Russian work on the Natural History of Khiva, prepared under General Kaufmann's directions some time since, but not yet published—owing, we may well suppose, to General Kaufmann's time being too much taken up with other more important matters. Figures and descriptions of it are given in Prof. Kessler's great work upon the results of the Aralo-Caspian Expedition. The fourth part of this work, published in January, 1877, contains not only full details as to this species, but also of a third Asiatic species of this genus—*S. hermanni*, Severzoff, likewise from the Oxus, without caudal filaments, which, however, is only based upon young examples. As already remarked by Dr. Günther in the note above referred to, the presence in the great Asiatic, as well as in the North American rivers, of this and another peculiar form of the limited group of sturgeons[1] is one of the highest importance in zoological geography. There can be little doubt that species of the genus *Scaphirhynchus* will also be found to occur in the great Chinese rivers, the Yang-tzé-kiang and Ho-ang-ho.

RESPIRATION OF AMIA.—*Amia calva* is a fresh-water fish of the United States. It is abundant in the Mississippi and its tributaries and in the great lakes. It attains a length of about two feet. Mr. Burt G. Wilder has published (*Proceedings* of the American Association for the Advancement of Science, 1877) an account of a series of experiments, which seem very conclusively to show that Amia not only exhales but also inhales air, and that this respiration is carried on by means of its swim (air) bladder. This is so much subdivided, that it will be remembered that Cuvier and others compared it to the lung of some reptiles. Experiments seem to show that the aerial respiration was more active when the water in which the fish lay was imperfectly aerated. The average of twenty-three measurements of the amount exhaled was thirteen cubic centimetres. The exhaled air contained about three per cent. of carbonic acid, and when the fish was fasting it contained at least one per cent. Amia displays great powers of endurance of privation of water. On one occasion a specimen was kept out of water for an hour and five minutes without any apparent discomfort or injury. During most of the time the gill-covers were tightly closed, but there were regular movements of the jaw, hyoid apparatus, and sides of the mouth.

CHILIAN BUTTERFLIES.—We have received a monograph of the butterflies of Chili, by Edwyn C. Reed, printed at the national press at Santiago de Chile. It contains descriptions of some sixty-six species, several of which are described as new, and the monograph is accompanied by three plates. We hope that we may from time to time be able to announce further new contributions to the natural history of this district, so well known by the elaborate "Historia fisica y politica" of Gay.

INSECTS IN TERTIARY ROCKS.—Mr. S. H. Scudder has recently published an account of some very remarkable forms of insects from the tertiary rocks of Colorado and Wyoming. These descriptions form Article xxiv. of the forthcoming vol. iv. of the United States Geological and Geographical Survey. Perhaps the most generally interesting insect described is a fossil butterfly (*Prodryas persephone*), which was found so perfect as to allow of the description even of the scales of the body and wings. It is the first butterfly fossil found in America, and, as only some nine species are known from the well-worked tertiary strata of Europe, it is undoubtedly of great value and interest. It shows a marked divergence from living types. A beetle is described (*Parolamia rudis*) which is rather of an Old World than of a New World type. A fly (*Palembolus florigerus*) is interesting not only as representing a highly-specialised type hitherto unknown in America, but as showing how the semblance of an original vein may be formed in a wing out of mere fragments of distinct veins. Masses of eggs of a species of Corydalites are also described as the first insect eggs found in a fossil state.

ON THE RELATIONS OF RHABDOPLEURA.—Prof. Allman believes that the very anomalous characters of this curious polyzoon genus (*Rhabdopleura*) admit of being derived from the typical confirmation of a polyzoon by certain easily understood modifications. One of the most puzzling of those characters is the apparent absence of a tentacular sheath. He maintains that the endocyst is really represented by the contractile cord which seems to take the place of the funiculus in the fresh-water polyzoa, but with which it has nothing to do. In *Rhabdopleura* the endocyst has receded from the ectocyst, and in its posterior part of the approximation of its walls, and the consequent nearly complete obliteration of its cavity has become changed into the contractile cord. Anteriorly, it spreads over the alimentary canal of the polypide, to which it becomes closely adherent, and here represents the tentacular sheath. Still more posteriorily the endocyst undergoes even greater modification, for the contractile cord becomes chitinised and converted into the firm rod which is found running through the stem and branches of the older parts of the colony, and which still presents in its narrow lumen a trace of the original cavity of the endocyst. The shield-like appendage which is attached to the lophophore is one of the most remarkable features in the genus. G. O. Sars regards it as representing the epistome of the Phylactolæmatous polyzoa, but this view is entirely opposed by the history of its development. Prof. Allman, by tracing its development in connection with that of the polypide has arrived at the conclusion that it is formed as a primary bud from the modified endocyst, and that in its turn it gives origin to a bud of the second order, which becomes directly developed into the definite polypide. The primary or scutiform bud continues for some time to increase in size with the developing polypide which it considerably exceeds, but is at last surpassed by the latter. It never disappears, however, but ultimately remains in the condition of a subordinate appendage of the polypide to which it had given origin. We have thus in the life-history of *Rhabdopleura* an alteration of heteromorphic zooids. The first term, however, in the genetic series, the direct product of the sexual system is as yet wanting, no trace of this system having hitherto been discovered in *Rhabdopleura* (Linnean Society of December 19, 1878).

GEOGRAPHICAL NOTES

M. BRAZZA and Dr. Ballay, the two Ogowé explorers, have arrived in Paris. M. Brazza is now preparing a map showing his discoveries in West Africa. It shows that the Ogowé issues from a large chain of mountains, and is formed by a number of rivulets descending from the high regions. The explorers suppose that a large part of the water filling the bed of the Ogowé issues by subterranean infiltrations from the Congo Basin. MM. Brazza and Ballay are led to this conclusion by the belief that the Congo is to be found on the other side of the range of mountains mentioned. They were unable to make a direct verification of this assumption, on account of the hostility evinced by the native tribes, who are of the most warlike disposition. It was with the utmost difficulty that the French explorers escaped from the hands of these barbarians, whose war-cries, arms, and canoes present striking resemblances to the ferocious

[1] Of the Sturine genus *Polyodon*, or Shovel-nosed Sturgeons, one, *P. folium*, occurs in the Mississippi, and a second, *P. gladius*, in the Yang-tzé-kiang.

blacks fought by Stanley. The Central Section of the Paris Geographical Society has decided to give to MM. Brazza and Ballay the great gold medal for 1879. Some members proposed to give it to Nordenskjöld, but the prolongation of his voyage, owing to his detention in Behring's Straits, was considered sufficient reason to adjourn Nordenskjöld's claims to 1880.

MANY proposals have been made for a new initial meridian to be adopted by all nations, but no satisfactory solution has yet been reached. The present state of things is very confusing, with nearly as many different initial meridians as there are civilised countries. In *L'Exploration* M. de Beaumont proposes the adoption of a zero passing through Behring's Straits and down the Pacific, its antemeridian passing through the centre of Europe and Africa; but, indeed, any universally-adopted zero would be better than the present confusion.

THE capitalists of Liverpool and Manchester, finding so many of the old markets shut against their enterprise, propose making a railway 500 miles long, from Zanzibar to the south end of Victoria Nyanza, to develop the trade of Central Africa. In the speeches on the subject at Manchester great ignorance was shown of the geography and hydrography of the region in question, and if only a desire to develop the resources of Africa is at the bottom of the movement, it is quite unnecessary to spend a million of money on a railway. With the magnificent water-way explored by Stanley and other travellers, and with the help of either Indian or tamed African elephants, the resources of Central Africa could be quite adequately developed for many years to come.

IN the January number of Petermann's *Mittheilungen* Dr. Gerhard Rohlfs gives the results of his search, during his last journey in the Libyan Desert, for the supposed empty river-bed of the "Bihâr-Bilâ-mâ." He discusses the chief references to this supposed extinct river, and concludes from his researches that there is no warrant for placing its dried-up bed on our maps. The same number contains a fine map of the region about the sources of the Oxus, with short explanatory text by Dr. Behm, and a map of North Siberia, showing Nordenskjöld's track from the Yenessei to the Lena. Accompanying the latter are German translations of the letters of various members of the expedition.

A CONTRACT has been concluded by M. Sibiriakoff, of Irkutsk, in Siberia, with the firm of Kockum, whereby the latter are to build him a steamer of 350 tons burden, for the purpose of going to the assistance of the *Vega*. It is expected that the steamer will be ready soon enough to start, fully equipped with provisions, in time to reach Behring's Straits, by way of the Suez Canal, next August, in order to assist Prof. Nordenskjöld and his companions. The vessel will afterwards trade to the Lena, and, if possible, even to the Yenessei.

AN Italian traveller, Manzoni, made a journey of some importance in Yemen, Arabia, in 1877, the results of which appeared in the *Exploratore*. In June last Manzoni commenced a second journey from Aden northwards to Asir and eastwards to Hadramaut. After visiting several places of interest he arrived in Sana, where, according to last reports, we learn from Dr. Behm's summary, he was ill. This exploration is supported by the Italian *Cosmos*.

THE last number of the *Isvestia* of the Russian Geographical Society contains an important paper by M. Maieff, giving an account of his journey last summer to South Bokhara. M. Maieff describes the various *beckdoms* or subdivisions of Bokhara, their productions, trade, and people, their chief physical features and hydrography. He concludes by some important information on the various routes from Guzar to the Amu Daria and Afghanistan.

A LETTER received from M. Oshanin, from Turkestan, announces that he has just returned from his great journey to Karataghin. He has discovered a very fine glacier, which he has called by the name of the late Fedchenko. This is the third locality bearing the name of the traveller: M. Ujfalvy has called the Lake Kutban-kul "Lake Fedchenko," and M. Maieff has given the same name to one of the peaks of Ghissar.

THE GEOLOGICAL HISTORY OF THE COLORADO RIVER AND PLATEAUS[1]

FOR convenience of geological discussion, Prof. Powell has divided that belt of country which lies between Denver and the Pacific, and between the 34th and 43rd parallels, into provinces, each of which, so far as known, possesses structural and topographical features which distinguish it from the others. The easternmost he has named the Park Province. It is characterised by lofty mountain ranges, consisting of granitoid and metamorphic rocks pushed upward and protruded through sedimentary strata, the latter being turned upwards upon the flanks of the ranges and their edges truncated by erosion. The generalised transverse section, on the assumption that the sedimentaries, prior to uplifting, were continuous across the mountains, is that of a broad and extensive anticlinal, sometimes profoundly-faulted parallel to the trend, the sedimentary strata which may once have extended across being removed by erosion. The intervening valleys still retain the entire sedimentary series. This form of mountain structure, with its resulting topographical features, gradually passes, as we go westward, into another type, arising from the decreasing frequency of the greater displacements or differential vertical movements of the earth's surface; but most frequently the dislocation is a combined monoclinal and a fault, or series of faults, with all shades of relative emphasis. The small departure from horizontality amid great general displacement is a strong trait, and justifies the name which has been applied to it by all observers with one accord—the PLATEAU COUNTRY.

West of this province lies a third one—the Great Basin. It is characterised by short, jagged mountain ridges, separated by goodly intervals of barren plains. These ridges are usually produced by the up-lifting of the strata along one side of a fault. Sometimes the faults are multiple, that is, consist of a series of parallel faults, the intervening blocks being careened in the same manner and in the same direction. This repetitive faulting is of very common occurrence. Other modifications, and even different types of structure, are presented; but there is throughout the Great Basin a striking predominance of monoclinal ridges, in which one side of a range slopes with the dip of the strata, and the other side slopes across their upturned edges. The forms impressed upon these masses by erosion are rugged, bristling, and sierra-like, and their peculiarities are aggravated by the fact that before these mountains were brought forth the platform of the country from which they arose had been plicated and the plications planed down by erosion. The Basin is the oldest western land of extensive area. Its final emergence was not later than Jurassic, and may have a still older date.

Between the Plateau and Park Provinces there is no definite boundary. Gradually as we proceed westward from the Parks of Colorado the valleys widen out and expand into a medley of terraces, bounded by cliffs, which stretch their tortuous courses across the land in every direction, yet not without system. The boundary separating the Plateau Province from the Great Basin, on the contrary, is abrupt. In many parts of its extent it seems almost possible to hurl a stone from one province to the

[1] By Capt. C. E. Dutton, U.S. Army, Assistant-Geologist U.S. Survey o the Rocky Mountain Region, under Prof. J. W. Powell, in charge.

other. Still there is a border country where the plateaux take on a type of structure which suggests the Basin type, though never to be confounded with it. Powell has given it the name of Kaibab structure, and through it the Grand Cañon of the Colorado cuts transversely. This structure extends northward from the Grand Cañon more than 250 miles, reaching within 100 miles of the Uintas, or even nearer than that. Between the great faults tabular masses have been uplifted to the average altitude of 11,000 feet, with grand valleys between them.

To the eastward of these high plateaus is spread out a wonderful region. Standing upon the eastern verge of any one of these, where the altitude is nearly 11,500 feet, the eye ranges over a vast expanse of nearly level terraces bounded by cliffs of strange aspect (Fig. 1). They wind about in all directions, here throwing out a great promontory, there receding in a deep bay, but continuing on and on until they sink below the horizon, or swing behind some loftier mass, or fade out in the distant haze. Very wonderful, too, is the sculpture of these majestic walls.

FIG. 1.—Bird's-eye view of Cliffs of Erosion, showing the Shin-ar-Ump Cliffs, Vermilion Cliffs, and Gray Cliffs, in order from Right to Left.

Panels, pilasters, niches, alcoves, buttresses, needing not the slightest assistance from the imagination to point the resemblance—grotesque colossal forms neatly carved out of solid rock, endless repetitions of shapes, which pique the fancy to find analogies, are presented to us on every hand, and fill us with wonder as we pass. But of all the characters of this unparalleled scenery, that which appeals most strongly to the eye is the colouring. The gentle tints of an eastern landscape, the rich blue of distant mountains, the green of summer vegetation, the subdued tints of hill-side and meadow—all are wanting, and in their place we behold belts of fierce, staring red, yellow, and toned white, which are intensified rather than alleviated by alternating belts of dark iron-gray. The Plateau Country is the land of cañons. Gorges, ravines, cañadas, are found in every high country, but cañons belong to the region of plateaus. Like every other river the Colorado has many tributaries, and in former times

had many more than now; and every branch and every twig of a stream here runs in a cañon. The land is honey-combed with them. To cross it, except in certain specified ways, is a feat reserved exclusively to creatures endowed with wings. The region is a desert of the most formidable description. A few attenuated streams

FIG. 2.—Grand Cañon of the Colorado (6,200 feet deep).

meander through it, but usually in cañons of which the bottoms are somewhere between the earth's surface and centre. The springs will not average one to a thousand square miles. But in the High Plateaus, at levels above 7,500 feet, we find a moist climate, exuberant vegetation, and hundreds of sparkling streams.

During Cretaceous times, the Plateau Country was a marine area. After 4,000 feet of Cretaceous strata were

deposited, a large portion, and perhaps the whole of this region became, for a time, land, and the uplifting was attended by considerable dislocation and flexing of the strata. In numerous localities the Cretaceous strata are seen to be denuded, and the lowest Tertiary beds lie across the bevelled edges. This uplifting took place after the deposition of a group of beds which in part, at least, are the equivalents of those which King and Hayden have named the Laramie Group. I accept the verdict of Marsh, Meek, King, and Powell, that these beds belong to the local Cretaceous series, and reject the decision of Hayden, that they are Tertiary. Thus the close of the Cretaceous is marked by a physical break separating it from the local Tertiary series by widely distributed unconformities.

After an unknown interval of denudation immediately following the close of the Cretaceous period the region was again submerged, and then began the deposition of that remarkable series of Eocene beds which form such a striking feature in the stratigraphy of the peripheral parts of the Plateau Country. Around the southern flanks of the Uintas their aggregate thickness exceeds 4,000 feet, but southwestward the upper members at length disappear, and seventy miles north of the Grand Cañon only the lower portion of the local Eocene (the Bitter Creek of Powell or Vermilion Creek of King) remain; indeed, in the latter locality no later beds than the Bitter Creek were deposited. The evidence is now conclusive that the Bitter Creek series stretched more than a hundred miles across the Plateau Country, covering, doubtless, its entire extent, while the middle and later Eocene covered smaller areas to the northward. Only marginal remnants of these huge deposits now remain. The heart of them has been eroded and swept away. Just at the commencement of the Tertiary periods the Plateau Country was covered with brackish water, having perhaps an analogy to the Baltic or Euxine, but after the accumulation of a few hundred feet of deposits the region became a vast inland lake. Its northern shore was along the base of the Uintas, which had then apparently gained their first elevation. Its north-western shore, by a coincidence which can hardly be accidental, lay along the identical boundary which now sharply separates the Plateau Country from the Great Basin, and the latter was one of the mainlands which furnished the sediments of the lake. From the angle where the Uintas join the Wasatch it is possible to trace this shore line more than 300 miles south-westward into Arizona with certainty, and to point out its principal bays and headlands, and even to locate the sites of some of the ancient river channels through which the lower Eocene sediments were brought down. The eastern, south-eastern, and southern margins, and the remainder of the south-western margin, remain to be determined by future exploration. At length, after one-third to one-half of the lacustrine beds had been laid down, there began a series of events which has developed the physical features of the Plateau Country, and which has pursued an unbroken course to the present time, and which even yet may not have culminated. Then began that uplifting which has raised the Plateau Country more than 13,000 feet on an average. Then, too, began a marvellous erosion which has cut down the mean level about one-half that amount, leaving the present mean altitude nearly 6,500 feet. At the inception of this process the lake began to dry up, the south-western portion now drained by the Lower Colorado being the first to emerge. Gradually through the succeeding periods the lake contracted its area, withdrawing northward to the Uinta Mountains, where, at the close of the Eocene, it disappeared.

We are now in a position to trace the origin, growth, and history of the Colorado River, if not from the beginning, at least from an epoch near its beginning. Its creation was not the event of one epoch, but a gradual process extending through several periods. The lower course, extending from the mouth of the Virgin to the Pacific, is the oldest portion, and makes its appearance in geological history a little before, but very near, the middle Eocene. Whether it existed before this epoch is not beyond doubt, but probably it did. But earlier than the Tertiary periods it cannot go; for it is certain that up to the close of Cretaceous times the ocean flowed over its track. When the Plateau Country was first isolated from the ocean it became a brackish Euxine, and may be presumed to have had a Hellespont somewhere. It soon after became an inland lake and must have had a St. Lawrence to keep its waters fresh. There can be little doubt that in the middle Eocene the outlet was the lower course of the Colorado. Whether the lake prior to that had some other outlet which it abandoned for this one is an open question, with the probabilities (on general principles) in favour of the negative. But the question is of no great importance.

The growth of the Colorado may be illustrated by considering what might happen to the St. Lawrence if the whole region of the Canadian lakes were uplifted two thousand feet. In no great length of time Ontario would be drained by the St. Lawrence, lowering its channel, and that river would become one with the Niagara. The same process would be repeated at Erie, Huron, and Superior, the lakes vanishing and leaving only a great river with many branches. Such was the origin of the Colorado; first a Hellespont, then a St. Lawrence, then a common but rather large river heading in the interior of a continent. Its principal branch, the Green River, cuts through the Uinta mountains by the Flaming Gorge and Cañon of Lodore. A second lake, apparently coeval with the one we have just discussed, lay to the north of that range and poured its waters through these gateways into the southern lake. What other bodies of fresh water may have been connected with either of these it is impossible to say at present.

At the epoch when the desiccation was completed it is not probable that the cañons had any existence, for the indications are that the elevation of the country at the commencement of the Miocene period was not great. Conditions favourable to cañon cutting are highly exceptional, and there is no évidence that this exceptional combination of conditions existed at that time, while there is much evidence that it did not. That the conditions, however, were favourable to a rapid rate of erosion is highly probable. But the forms which it would produce might be more nearly analogous to those which may be observed in eastern Ohio and western Pennsylvania. That the climate was moist and sub-tropical is rendered probable by the vegetable remains found in the surrounding regions, and it is only rational to suppose that such a climate in a moderately elevated region would yield such results as may be seen in countries similarly conditioned. Whether the valleys were broad or narrow, abruptly walled or gently sloped, matters little. It is almost certain that they were not deep. The great cañons which we now see had not even been commenced, although they were foreshadowed, and the train of events which was to produce them at a later period had started into activity.

The history of the Colorado and its drainage system during Miocene time must be spoken of only in general terms. In truth during this great age there is no evidence of the occurrence of any critical event aside from the general process of uplifting and erosion which affected the region as a whole. The vast erosion of this region has swept away so much of its mass that most of the evidence as to the details has vanished with its rocks. But the more important features of the work, its general plan in outline, have left well-marked traces and these can be unravelled. It was a period of slow uplifting, reaching a great amount in the aggregate, and it was also

a period of stupendous erosion. The uplifting however was unequal. The comparatively even floor of the old lake was deformed by broad gentle swells rising a little higher than the general platform. In consequence of their greater altitude these upswellings at once became the objects of special attention from the denuding agents and were wasted more rapidly than lower regions around them. Here were formed centres or short axes from which erosion proceeded radially outwards, and the strata, rising very gently towards them from all directions, were bevelled off. As the erosion progressed so also did the uplifting of these local centres or axes, thus maintaining the maximum erosion at the same localities. It is a most significant fact that the brunt of erosion is directed against the edges of the strata and not against their surfaces, provided the stratification is but little disturbed. Usually such an uplift will have one diameter longer than another, and we may call the greater the major-axis. The strata dissolve away in all directions by the waste of their edges, and after the lapse of long periods the newest or uppermost strata will be found encircling the centre of erosion at a great distance—the next group below will encircle it a little nearer, and so on.

This has been the history of each of the sub-divisions of the Plateau Country. Upon the western and northern sides of the Colorado five of these centres are now easily discerned. By far the largest and probably the oldest is around the Grand Cañon. All these had their inception in Miocene time, though the one around the Grand Cañon may go back into the upper Eocene. The district known as the San Rafael Swell is by far the best suited for study.

If we stand upon the eastern verge of the Wasatch Plateau and look eastward we shall behold one of those sublime spectacles which fill even the calmest observer with awe and amazement. From an altitude of more than 11,000 feet the eye can sweep a semicircle with a radius of nearly seventy miles. It is not the wonder inspired by great mountains, for only two or three peaks of the Henry Mountains are well in view, and these with their noble alpine forms seem as strangely out of place as Westminster Abbey would be among the ruins of Thebes. Nor is it the broad expanse of cheerful plains stretching their mottled surfaces beyond the visible horizon. It is a picture of desolation and decay; of a land dead and rotten with dissolution apparent all over its face. It consists of a series of terraces all inclining upwards towards the east. We stand upon the lower Tertiary rocks and right beneath our feet is a precipice leaping down across the edges of the level strata upon a terrace 1,200 feet below. This cliff stretches away northward gradually swinging eastward, and finally southward, describing a rude semicircle around a centre about forty miles to the eastward. At the foot of this cliff is a terrace about six miles wide of upper Cretaceous beds inclining upwards towards the east very slightly, and at that distance it is cut off by a second great cliff plunging down 1,800 feet upon middle Cretaceous beds. This second cliff describes a smaller semicircle concentric with the first. From the foot of the second cliff the strata again rise through a width of about ten miles and are cut off again by a third series of cliffs as before. There are five of these concentric lines of cliffs. In the centre there is an elliptical area forty miles long and twelve to twenty wide, its major axis being north and south, which is as completely girt about by rocky walls as the valley of Rasselas, but such walls as Dr. Johnson never dreamed of. We have given it the name of the Red Amphitheatre. Yet, if we look back to Eocene time, we shall find that the whole stratigraphic series, up to the Eocene inclusive, covered this amphitheatre. Nearly 10,000 feet have now gone, and the floor is near, or quite, at the summit of the Carboniferous rocks. At present the Amphitheatre is drained by two streams which cut across it and find their way, one into the Green, the other into the Colorado, below the junction of the Grand.

Still more vast is the erosion which has taken place from the vicinity of the Grand Cañon. Here the Carboniferous strata form now the floor of the country, though a few patches of Trias still remain in the vicinity of the river. But the main body of the Triassic rocks stands now fifty miles north of the river, and beyond them, in a series of great terraces, rise the Jurassic, Cretaceous, and Tertiary formations—the latter capped with immense bodies of volcanic rock. The greater part of the erosion was accomplished in Miocene time.

It will be seen that these local uplifts are important in determining the subdivisions of the area and the distribution of the maxima and minima of degradation. We may see here a correspondence which is worthy of close attention. Those areas which have been uplifted most have been most denuded. I have asked myself a hundred times whether we might not turn this statement round, and say that those regions which have suffered the greatest amount of denudation have been elevated most, thereby assuming the removal of the strata as a cause and the uplifting as the effect; whether the removal of such a mighty load as ten thousand feet of strata from an area of ten thousand square miles may not have disturbed the earth's equilibrium of figure, and that the earth, behaving as a *quasi*-plastic body, has reasserted its equilibrium by making good a great part of the loss by drawing upon its whole mass beneath. Few geologists question that great masses of sedimentary deposits displace the earth beneath them and subside. Surely the inverse aspect of the problem is *à priori* equally palpable. That some such process as this has operated in the Plateau Country looks at least very plausible, and, if there could be found independent reasons for believing in its adequacy, the facts certainly bear it out. Yet its application is not without some difficulties, and the explanation is not quite complete. Granting the principle, it will be still difficult to explain how these local uplifts were inaugurated; and we can only refer them to the agency of that mysterious plutonic force which seems to have been always at work, and whose operations constitute the darkest and most momentous problem of dynamical geology. On the whole it seems to me that we are almost driven to appeal to this mysterious agency to at least inaugurate, and perhaps in part to perpetuate, the upward movement, but that we must also recognise the co-operation of that tendency which indubitably exists within the earth to maintain the statical equilibrium of its levels. The only question is, whether that tendency is merely potential or becomes partly kinetic; and this again turns upon the rigidity of the earth. But it is easy to believe that, where the masses involved are so vast as those which have been stripped from the San Rafael Swell, and from the Kaibabs around the Grand Cañon, the rigidity of the earth may become a vanishing quantity.

Let us turn now to a law which forms a most important link in the chain of discussion—a law without a thorough comprehension of which the structural geologist in the Plateau Country would see very little except Sphinxes, but one which, when he has fully saturated his mind with it, will enable him to translate many mysteries. This law may be called the persistence of rivers. It is a very simple one, but its uses are wonderful; indeed those who have found it so invaluable in the Plateau Country often wonder why so little use has been made of it elsewhere. If the study of this region should accomplish nothing more than drawing this principle from its modest retirement and installing it in its rightful place in the logic of geology it will still have accomplished a great result. But the law has its limits, which we cannot overstep with safety.

Of all the changing features of a continent the least changeful are its great rivers. Undoubtedly rivers have

perished and undoubtedly they have shifted parts of their courses somewhat; but on the whole their tenacity of life is wonderful, and the obstinacy with which they sometimes maintain their positions is in powerful contrast with the instability of other topographical features. This characteristic, however, fails at low levels. A river near its mouth may often change its course; but where the country is high enough to enable it once to fasten its grip it will hold it, despite all the changes to which the surface of a continent is ordinarily subject throughout the term of its secular existence. Its stability and persistence will depend usually upon its altitude, or what amounts to the same thing, upon the rapidity of its slope. When that is small we may look for signs of inconstancy. Other conditions might be formulated which could affect it or modify it; but on the whole the fact remains that rivers have a remarkable power of maintaining their positions. It would be difficult to point out an instance where a great river has ever existed under conditions more favourable to longevity and stability of position than those of the Colorado and its principal tributaries. Since the epoch when it commenced to flow it has been situated in a rising area. Its springs and rills have been among the mountains and its slope has throughout its career been continuously though slightly increasing. The relations of its tributaries have in this respect been the same, and indeed the river and its tributaries have been a system and not merely an aggregate, the latter dependent upon and perfectly responsive to the physical conditions of the former. And now we come to the point. The Colorado and its tributaries run to-day just where they ran in the Eocene period. Since that time mountains have risen across their tracks, whose present summits mark less than half their total uplifts; the river has cleft them down to their foundations. The Green River, passing the Pacific Railway, enters the Uintas by the Flaming Gorge, and after reaching the heart of this chain, turns eastward parallel to its axis for thirty miles, and then southward, cutting its way out by the splendid cañon of Lodore. Then following westward along the southern base of the range for five miles, a strange caprice seizes it. Not satisfied with the terrible gash it has inflicted upon this noble chain, it darts at it viciously once more, and entering it, cuts a great horse-shoe cañon more than 2,700 feet deep, and then emerging, goes on its way. Thenceforward, through a tortuous course of more than 300 miles down stream the strata slowly rise—the river almost constantly running against the gentle dip of the beds, cutting through one after another, until its channel is sunk deep in the carboniferous. Further down, near the head of the Marble Cañon, the Kaibab rose up to contest its passage, and a chasm more than 6,200 feet in depth bears witness to the result. It is needless to multiply instances. The entire province is a vast category of instances of drainage channels running counter to the structural slopes of the country. I am unable to recall a single tributary to the right bank of the Colorado which does not somewhere, and generally throughout the greater part of its course, run against the dips. The northern tributaries of the Grand Cañon have their entire courses thus related. If we were to take the sums of the lengths of the river and its right hand affluents, we should find that at least three-fourths of that total length lay where the streams run against the dips.

It is clear, then, that the structural deformations of the region—the faults, flexures, and swells, had nothing to do with determining the present distribution of the drainage. The rivers are where they are in spite of them. As these irregularities rose up, the streams turned neither to the right nor to the left, but cut their way through them in the same old places. The process may be illustrated by a feeble analogy with the saw mill. The river is the saw, the strata are the timber which is fed against it. The saw-log moves while the saw vibrates in its place. The river holds its position almost as rigidly, and the rising strata are dissevered by its ceaseless wear.

What, then, determined the situation of the present drainage channels? The answer is that they were determined by the configuration of the old Eocene lake-bottom at the time the lake was drained. Then surely the water-courses ran in conformity with the surface of the uppermost Tertiary stratum. Soon afterwards that surface began to be deformed by unequal displacement, but the rivers had fastened themselves to their places and refused to be diverted. This, then, is the key which unlocks for the geologist the vestibule of the Plateau Country. The rivers were born with the country itself, they are older than its cliffs and cañons, older than its great erosion—the oldest things in its Tertiary history; nay, they are its history, which we may yet read imperfectly in their cañon walls. The mountains and plateaus are of subsequent origin. They arose athwart the streams only to be cleft asunder to give passage to the waters. The rivers amid all changes have ever successfully maintained their right of way. Such are the uses of the limited theorem of the persistence of rivers.[1] I shall not attempt to suggest how far it may be applicable to other regions, but I am confident that any geologist visiting the Plateau Country will be quickly overwhelmed with the conviction that it is true there.

In this connection it remains to add something to indicate the magnitude of the work accomplished, and the real extent of the obstacles which the Colorado has accomplished in maintaining its existence. In the Colorado itself, the maximum work has been done at the Grand Cañon (Fig. 2). This chasm is 217 miles in length, to which should be added properly the Marble Cañon above, 69 miles long, since the two are continuous, and their separation merely nominal. The average depth of the Grand Cañon is a little more than 5,200 feet—almost exactly one mile. Its maximum depth through the Kaibab Plateau is nearly 6,300 feet, this depth being maintained approximately as the river runs for about fifty miles. Surely it might be thought that to cut such an abyss is work enough in the life of one river however ancient of days. But the summit of the Kaibab is Carboniferous limestone. When the river began to run in this part the whole local Mesozoic and lower Eocene series rested upon the site of this plateau, but have since been swept away together with a part of the Carboniferous rocks. The river has cut through the entire fossiliferous system of strata and now runs 2,000 feet deep in the archæan. The total thickness of the fossiliferous system here is, or rather was, very nearly 17,000 feet. Hence in its lifetime the river has cut through about 19,000 feet of strata. Through the remainder of the Grand Cañon the total cutting has been from 2,000 to 3,000 feet less. As we ascend the river the amount diminishes—not regularly but with local maxima—until we approach the southern base of the Uintas. The principal branch, the Green River, has cut its channel into the quartzites of this range even more deeply than the Colorado in the Kaibab. Yet strangely enough the instant the Green is clear of the mountains it enters a long stretch where the cutting has been practically nothing. The explanation of this contrast will become obvious to the geologist by a mere reference to the fact that where the cutting has been zero the locality has been always at the base level of erosion, and never above it. Only those parts which rise above the base level are cut down.

(*To be continued.*)

[1] Mr. Jukes employed the same principle in explaining some features in the lower courses of the rivers of Ireland. *Quart. Journ.* Geol. Soc. of London, xviii. (1862), 378, quoted in Jukes and Geikie's "Manual of Geology," Third Edition, p. 454. [But the idea may be found in Hutton's great work the "Theory of the Earth," and in Playfair's "Illustrations." See particularly pp. 102 and 350 *et seq.* of the latter work.—ED.]

THE BRITISH MUSEUM LIBRARY

WHAT sort of reference library can be provided in connection with the natural history collections when they are moved from the British Museum to South Kensington? is a subject now under consideration. It is stated on good authority that, so far as the building arrangements at Kensington go, no provision whatever has been made for library space, and that in the Act passed at the end of last session to enable the trustees to move the collections, a reference library seems to have been entirely overlooked. That Act has, however, been the subject of a resolution by the General Committee of the British Association, requesting the Council to take such steps in the matter as they might deem expedient; and although the resolution had principal reference to the administration of the collections, its force extends equally to such an important matter as a library, should the Council "deem it expedient" to include that subject.

Whatever may be the decision as to what part of the library can be transferred to Kensington, or what ought to be transferred, it is only the works relating to biological studies that will be essential there, and it is only these, therefore, that are likely to be the subject of inquiry. But it might, perhaps, lead to changes of great value to those who use the British Museum Library for the purposes of referring to the literature of science in its other branches as well, if the inquiry could be extended to include the question of the actual state of this literature, which is available for use at the Museum. Whether it should be expected that the national library should contain as complete a collection as possible of scientific publications, or whether those who wish to consult them ought to belong to several of the incorporated learned societies, and use their libraries, is a separate question. When this question is considered, if it has to be considered at all, it must not be forgotten that no one society has anything like a comprehensive collection of scientific works, each society aiming at completeness in its own subjects; that to belong to several societies is not within the means of every student; and that, as one of the advantages of these societies is that members may take books away, no one can be sure of finding on the shelves what they may wish to consult.

But quite apart from such a question as this it would be of great use, with a prospect of effecting changes, to know what is the actual state of the British Museum library as regards scientific literature.

Only those who have had occasion to work at the library can have any idea how incomplete it is in this department, or what a wearisome toil it is, in consequence of the system of cataloguing adopted, to find whether a work they wish to consult is or is not there. If the experiences of those who have had occasion to use the library for such purposes could be collected, the probability is that it would be found that from a third to a half of the works asked for were not obtainable there. This may seem at first sight a very surprising assertion to make, but there is good reason to believe it true. What the Museum does or does not contain can, however, be known only by an inquiry, especially directed to ascertain the facts. A reference to the catalogue, as at present arranged, is quite inadequate to give an answer. The officials themselves could not tell from it what they have and what they have not. For example: suppose a particular volume of the Reports of the United States Geological Survey of the Territories is wanted, a reference to the catalogue will not tell whether it has been received or not. The catalogue simply gives the information that the series is on a particular shelf. If a ticket for the whole series is filled up according to the requirements of the reading-room regulations with the press mark, the title, and Washington, 1873, &c., 4° added, then it will be found when the books are brought to the reader's seat, that only volumes two, six, nine, and ten of the whole series are there. This illustration applies to all publications which are issued in a series either by societies or by government departments. To ascertain, therefore, what is the incompleteness of series of which some numbers find a place in the catalogue, it would be requisite, if a reader undertook such an investigation, to write tickets for every series separately, to have all the numbers brought, and then to make note of the gaps. Such a work is rather the duty of the officials than of readers, but, as already stated, it would require a special inquiry, whether made by readers or by officials, to ascertain what is really the state of the British Museum library as to the literature of science.

It must be borne in mind that an important part, perhaps the most important part, of the literature to which a worker in science wants to refer, is that which is in the series of the different societies and government departments, and it is just in this that the British Museum is weakest, and in which it might be supposed a remedy might be most easily found. To fill up gaps of old standard works out of print is not very easy. Chances of sales of libraries must be carefully looked out for to effect this, but the current literature of societies and of departments is more easily secured.

An inquiry into the state of the scientific literature at the Museum, and the facilities for its use, might be advantageously directed under three distinct heads, each of which has an important bearing on meeting the requirements of those who wish to consult the collection:—

1. As to the incompleteness of series.
2. As to the length of time that elapses between the publication of a number and its being obtainable at the Museum.
3. As to the method of cataloguing.

As regards (1) incompleteness of series, there is no reason to believe that it is confined to publications referring to any particular branches of science more than others. For example, to take a few cases at random, there are only three volumes of the reports of the state of the Brussels Observatory; there is only one part of the long series of reports on the health of the City of London; there are three volumes wanting of the Report of the Commissioners on the Sanitary Condition of the Labouring Population of Great Britain; the publications of the Geological Survey are very incomplete; there are none of the maps of the Water Supply Commission nor of the Coal Commission; and so on. To attempt to give a list of what is known to be wanting would not be of much use for the reason stated above, that nothing short of a full inquiry into the matter could make known what is the real state of affairs. When a question is asked as to why certain volumes are missing, there is always one reply given—the publications of societies, home and foreign, are presented, and cannot be demanded, and as to the publications of Government departments, the Museum has no claim. If they happen to be sent to the Museum they are received, but if not, it would seem that under the existing system there is no help for it.

As regards (2) the length of time before a volume that is sent can be had for reference, it may be safely put at from one to two years. If a question is asked, how it is that such delays occur, a very general answer is that some societies are very irregular in sending their publications, but when such cases as this occur—that at the Museum a reader cannot now have a volume of the *Bulletin* of the Brussels Academy later than 1876, while at another public museum, the Patent Office Library in Southampton Buildings, he can have it up to June in this year—it seems to point rather to some feature in the administration of the Museum as the cause. Many cases of this kind might be quoted if it were required to establish the fact. It is, no doubt, a wise arrangement that novels and magazines that can be seen at any circulating

library should not be available for use at the Museum till a year after publication. But the case is very different with the class of scientific publications now referred to. Of the foreign and colonial publications not many copies of each issue reach this country, and in some cases they can be seen only by the courtesy of an officer of a society that has received a copy. Then, again, not only the amount of interest taken in any particular communication, but sometimes its value, is changed in twelve months. It has been already said that perhaps the question may be raised whether the British Museum is the place to expect to see recent scientific publications, but it would be well if its present state were in any case known.

Then (3) as to the method of cataloguing. The use of the catalogue is of course to enable a reader to find the press mark of the books he wants with the least possible delay. There may be differences of opinion as to the extent to which a catalogue should help a reader, but the facts as regards the British Museum are these. Scientific publications which are not books, magazines, or newspapers, are for the most part grouped under "Academies." The majority of those which do not fall under this head are to be found under the titles of the government departments by which they are issued. In order not to waste time over the catalogue the reader must know certain particulars about the work he wants. If it is issued by a British government department he must know whether it has or not been presented to Parliament. For example, the pathological researches of Dr. Sanderson and Dr. Klein were addressed, through the Local Government Board, to the Lords of the Privy Council; the geological work of the Survey is through the Science and Art Department of the Committee of Council on Education, also under the Privy Council. The pathological researches are, however, presented to Parliament, and the volume containing any particular part of them must be, therefore, looked for under "Parliamentary Papers," while the geological work is not presented to Parliament, and must therefore be looked for under "Great Britain and Ireland—Geological Surveys." In the former case it is requisite to know beforehand in what year the papers were included; in the latter case the memoir to a map may be obtained in this way, but no clue is given as to how to obtain the map itself. (If the press mark for the map is searched for in the map catalogue, cross-references lead to "World—miscellaneous —*see* geographical and geological"). The difficulty of knowing whether a work has or has not been presented to Parliament is sometimes great. For example, some of Mr. Simon's Cholera Reports are included under the Registrar-General's returns and are therefore to be looked for among "Parliamentary Papers;" while the celebrated 1848 Report, which seems somehow not to have been presented, has to be found in the general catalogue under the name Simon, John. This is, of course, quite consistent with the method adopted. As it is with the British so with the foreign publications of departments, it is requisite to know to what department a report is sent. An entomologist may be surprised that to get at some of the United States' publications giving monographs on certain groups, he has to get his press-mark from the catalogue under United States—Department of the Interior—Geological Surveys of the Territories—yet such is the case. And this, too, is quite consistent with the method of cataloguing adopted.

If the work to be consulted is issued by a learned society it will probably be found entered under "Academies." In order to find it in the catalogue the exact title must be known. For example, it is no use to look for a Society of Arts' publication under "Society of Arts." it is requisite to go in the catalogue from "of" to "for" as the full title is "Society for the Promotion," &c. It is also essential to know whether a society has the prefix kaiserliche or kaiserliche-königliche, or königliche, or Imperiale, or Royal, or British, or the title of any nationality or town. It is also requisite to know where the work is published, as the grouping is according to the plan, Academies at so and so. That a reader should first have all this information about a work he wants to consult may be very reasonable, for perhaps the collection at the Museum is too extensive to admit of printing, as the Patent Office library does, a compact and convenient "list of the scientific and other periodicals and transactions of learned societies in the free library."

But it is after a reader has found in the catalogue the title of the society that his real trouble begins. It might reasonably be supposed that the first entry under the name of the society would be the memoirs, transactions, or journal, as the case may be, of the society. That is not the British Museum plan. First are given the press marks of charter, laws, bye-laws, notices of annual meetings, lists of members, and such like things, and page after page has to be turned over to get to the publications of the society. If there are two sets of publications, such as quarto transactions and an octavo journal, these are generally separated by some pages of other references. To take a very familiar case, the memoirs of the French Académie are of course frequently referred to. After the reader has found the right volume of the catalogue containing "Academies at Paris," and has found Académie des Sciences, he will have to look on one page for vols. i. to xi., then, eight pages further on, for vols. xii. to xxiv., and then, further on again, xxv. onwards. It is difficult to imagine what principle is supposed to be followed, or what is gained to a reader by such a plan. If it should happen that the reader does not know that one series of the memoirs contains the communications of members and another series the communications of "Savans Étrangers," he will still have more trouble in obtaining what he wants. Or take an English case. Suppose a reader wishes to refer to an account of a paper communicated to the Ashmolean Society. He will find, under that heading, entries of an account of the Society, old notices of meetings to be held (handbills), rules, &c., but no intimation of whether the Society issues any transactions.

In short, with all the societies, the entries of the regular publications are so mixed up with rules, list of members, bye-laws, &c., that it takes some time, after the right volume and right page have been found, to turn out their press mark. Again, it is not always easy for a reader to know what is classed as an academy and what is not. An account of a communication given before the Royal Institution in Albemarle Street must be sought in the journal catalogued under academies, while one given before the London Institution in Finsbury Circus, though equally a chartered society, must be sought under "London." Or again, how should the records of observations be catalogued? under periodical publications? under academies, or in the general catalogue. The practice differs in different cases.

Were it not for the kind and ready assistance given in cases of need by the reading-room superintendent and his assistants, a reader would be often quite unable to see what he needs.

THE "GRAHAM" LECTURE AND MEDAL

SOME time ago the Chemical Section of the Philosophical Society of Glasgow had under consideration the propriety of raising a fund for the encouragement of original research. The movement soon began to assume practical shape, and in course of time the fund was found to have reached to nearly 300*l.*, the subscribers being chiefly well-known chemical manufacturers and merchants in Glasgow and the west of Scotland. For a time there was

some difference of opinion as to whether the money subscribed should be invested for the purpose of endowing a lectureship or exclusively for the awarding of medals for original research. It was eventually agreed, however, that two-thirds of the fund should be appropriated for lecture purposes and one-third for medal purposes, and it was likewise determined that the medal should bear the name of the "Graham" Medal; and that one triennial lecture should also be designated the "Graham" Lecture, both lectureship and medal being instituted in commemoration of the eminent services of a former citizen of Glasgow and member of the Philosophical Society, the late Thomas Graham, Master of the Mint, so distinguished for his researches in chemistry and physics.

As the scheme is now in such a complete state that it may be announced to the scientific world, we mention a few facts of interest in regard to it.

Through their president, Mr. James Mactear, of St. Rollox Chemical Works, the Council of the Chemical Section have been successful in obtaining from Her Majesty's Mint a valuable die of Prof. Graham, and the authorities of the Mint have agreed to strike the medal free of charge, the Trust Fund supplying the necessary gold for the purpose. The Council intend to award the medal at not less intervals than three years, in order that time may be allowed for papers to be brought forward of sufficient merit to justify them in making an award. It may be remarked that the medals, of not less value than 10*l.*, is to be awarded for the best original investigation in chemical physics or in pure or applied chemistry, which may be communicated to the Philosophical Society of Glasgow, or the Chemical Section thereof, during the three sessions preceding the award.[1] The Council of the Section will make the award, or it may be made by an equivalent body of local chemists of repute, with power on their part to remit the function to the Professor of Chemistry in University College, London, or to the Professor of Chemistry in the University of Edinburgh. Papers in competition for the "Graham" medal, may, we believe, be offered from any part of the United Kingdom; in other words, authors need not necessarily be members of the Philosophical Society of Glasgow, or of its Chemical Section. Dr. William Ramsay, University Laboratory, Glasgow, the present Secretary of the Section, will be glad to answer all inquiries in regard to the matter.

For the purpose of inaugurating the "Graham" lecture scheme in the most fitting manner possible, the Council of the Section have induced Mr. W. Chandler Roberts, F.R.S., the successor to Prof. Graham, as Chemist to the Mint, and for a long time his chief assistant in carrying out his later investigations, to deliver the first lecture, which is announced for Wednesday, the 22nd inst. Of course it is to be delivered in Glasgow. The subject is to be "Molecular Mobility, or some Forms of Invisible Motion," with special reference, doubtless, to the valuable physico-chemical researches instituted by Graham. It is the intention of the lecturer to exhibit and even to use a good deal of the apparatus employed by Graham, and now the property of Mr. Roberts.

"The fitness of things" in connection with the delivery of the inaugural "Graham" lecture is still further shown in the choice and consent of Mr. James Young, F.R.S., of Kelly, to preside on the occasion. There may be many readers of NATURE to whom it is not known that the gentleman just named was, when a very young man, a student in the evening popular classes conducted by Graham in the Mechanics' Institution and Anderson's College, Glasgow, whom he afterwards faithfully served as lecture assistant, first in Glasgow, and then in the laboratory of St. Thomas's Hospital, London. That he benefited by the scientific teachings of his great master is abundantly evident in the fact that he is himself the founder of one of our greatest chemical industries, namely, the manufacture of paraffin and paraffin oils—in a sense, the creation of the last quarter of a century, but already big with scientific and practical results. His devout respect for Graham's memory has since become almost a passion, and it is but proper that he should "assist" at this further effort to commemorate the great scientific triumphs of his teacher, master, and friend.

JOHN MAYER

[1] This is surely a mistake; why any limit?—ED. NATURE.

NOTES

AT the anniversary meeting of the Imperial Academy of Sciences of St. Petersburg, on December 29, 1878, it was announced that Mr. Hind, F.R.S., superintendent of the *Nautical Almanac*, had been elected a Corresponding Member of the Academy. Besides Mr. Hind there are in the list of Corresponding Members of this great Academy the names of Airy, Darwin, De la Rue, Frankland, Hooker, Huxley, Miller, Owen, Sabine, and Sylvester.

WE trust the subject discussed in our first article this week will meet with the attention it deserves in the proper quarter. It is clear that, by almost every civilised government but our own, the vast importance of meteorological observatories at high altitudes is recognised, and the universal value of weather forecasts is now taken as a matter of course. France has her Pic du Midi and Puy de Dôme, America her magnificently-appointed Pike's Peak, and, as our article shows, other countries in Europe have each one or more of these all-important lofty observatories; but, as usual, we are half-a-century behind. How valuable meteorological observations would be to the nation, on one or more of our loftiest Scotch mountains, any meteorologist can tell, and may be seen clearly enough from the article. We earnestly hope the question will not be allowed to subside, but will be persistently urged in the proper quarter as a matter of national importance. It would not take the price of a new gun to found such an institution as is wanted.

THE telegraph wires of Pic du Midi Observatory have been broken again for a number of days. Some anxiety was felt at Toulouse for the safety of General Nansouty, and a rumour spread that the house had been crushed by an avalanche descending from the rock at the foot of which it has been built for protection against the wind. M. Albert Tissandier was sent to reconnoitre with three mountain guides. On January 9, in the morning, he started from Bagnères. On the 10th, in the evening, he arrived at the observatory, where he found that the rumours spread in the plains were unfounded; General Nansouty was taking his readings. On the following morning M. Tissandier took some drawings, and on the 12th he returned to Bagnères. The telegraphic communications with Puy de Dôme were interrupted on the 11th, at the very time when they were restored with Pic du Midi.

A SUCCESSFUL experiment was made the other night at Liverpool Street station in electric lighting, the particular form used being that known as the "Farmer-Wallace." Several platforms were successfully lighted up, and only one or two minor and easily remediable drawbacks characterised the display. By means of a small electro-magnet on the top of the frame, carrying a clutch, the carbons are kept constantly adjusted, without interference. The gas companies have at last determined to show what they can really do in the way of illumination, and give themselves fair play in any comparison with electric lighting. The Phœnix Company, on Saturday night, lit up a part of Waterloo Bridge Road with gas of increased power, on an increased number of lamps, with special burners, in specially-arranged cages. The result was quite sufficient to

cause discontent with the present inadequate illuminating power of gas in street-lamps. The expense is of course greater, but we doubt if it would be so much as the cost of any satisfactory system of electric lighting; and perhaps, rather than run the risk of being relegated to the category of "lights of other days," the companies may, by a little pressure, be made to see the advisability of supplying better gas at even a cheaper rate than the present.

A NUMBER of friends and colleagues of the late Karl von Littrow, director of the Vienna Observatory, have had a medal struck in his memory, which may be obtained at a moderate cost from the publishing firm of Gerold and Co., Vienna. The face of the medal bears a portrait of von Littrow, and the reverse a view of the new Vienna Observatory.

M. DELESSE has been nominated a member of the Paris Academy of Sciences, in the section of Mineralogy, in place of the late Prof. Delafosse.

M. EDMOND BECQUEREL, who has been appointed vice-president of the Academy of Sciences for 1879, will act as president of the Academy in 1880, according to the constant custom. The president for 1879 is M. Daubrée, the celebrated geologist, who was nominated vice-president last year. M. Daubrée has been nominated president of the Central Section of the Geographical Society of Paris for 1879; M. Delesse, the newly-elected member of the Institute, one of the vice-presidents.

OUR readers will regret to hear that Prof. Clifford's health is still extremely delicate; he sailed for Madeira a few days ago, accompanied by Mrs. Clifford, in the hope that the genial climate would lead to improvement. We trust this hope will be realised.

THE Managers of the Royal Institution of Great Britain have decided that the next Actonian Prize shall be awarded to an essay illustrative of the wisdom and beneficence of the Almighty; the subject being "The Structure and Functions of the Retina in all Classes of Animals, viewed in relation with the Theory of Evolution." The prize is 100 guineas, and will be awarded or withheld as the managers shall think proper. Competitors for the prize are requested to send their essays (with or without their names being affixed) to the Royal Institution, addressed to the Secretary, on or before October 1, 1879. The adjudication will be made by the managers in 1879.

THE widow of Faraday died last Monday week.

IT seems to be acknowledged that the readings taken by the electrical instruments kept at Montsouris Observatory are not sufficient to give an accurate idea of the changes in the tension of the air. During the present period, when almost every fall of snow was observed during the night, the readings of the Montsouris Observatory gave no sign of negative tension. We are in a position to state that a self-registering apparatus would have been kept in operation from the beginning of last year, if it had not been required to send it to the Champ de Mars Exhibition for the instruction of visitors. M. Marie Davy is now engaged in putting into operation this apparatus. It should be stated that in 1873 a scientific delegate having been sent to England by M. Jules Simon, then Minister of Public Instruction, suggested that the self-registering instruments to be established in the French observatories, should be constructed according to the pattern adopted at Kew Observatory, so that comparisons should not be rendered impossible. The remarkable conclusions recorded by Mr. Whipple last week are an indication of the soundness of these suggestions.

THE winter has been so severe in France that the whole of the land on January 11 was transformed into a solid mass of ice, communication by rail, and even intelligence by wire becoming very difficult in the elevated parts of the country. The most extraordinary fall of snow recorded in the period was close to Montargis, where it accumulated to a height of 2 metres on a long narrow band of several kilometres long. In the meanwhile the largest rivers of the land overflowed, owing to the great rains which had been prevailing. The Seine reached an altitude of 6·21 metres at Pont Royal, the Loire was higher than on any year on record at Nantes, where the inundation was a public calamity; the increase of the Garonne and Rhône was only stopped by the freezing of the high lands.

AMONG the papers to be read at the forthcoming meetings of the Society of Arts are the following:—February 26, "Indian Pottery at the Paris Exhibition," by George Birdwood, M.D., C.S.I.; March 5, "The Social Necessity for Popular and Practical Teaching of Sanitary Science," by Joseph J. Pope, M.R.C.S.; March 12, "The Compensation of Time-keepers," by Edward Rigg, M.A.; March 19, "Economical Gardens for Londoners," by W. Mattieu Williams, F.C.S.; March 26, "The Treatment of Iron to Prevent Corrosion" (a second communication), by Prof. Barff, M.A. In the Chemical Section—January 30, "Gas Illumination," by Dr. William Wallace, F.R.S.E. In the Indian Section—January 21, "Quest and Early European Settlement of India," by George Birdwood, M.D., C.S.I.; February 21, "The Trade of Central Asia," by Trelawney Saunders. In the African Section—February 4, "The Opening of the District to the North of Lake Nyassa, with Notes of a Recent Expedition through that country," by H. B. Cotterell; March 18, "Some Remarks upon an Old Map of Africa contained in Janson's Atlas, published at Paris in 1612," by R. Ward; April 1, "The Contact of Civilisation and Barbarism in Africa, Past and Present," by Edward Hutchinson. Cantor Lectures—First Course, on "Mathematical Instruments," by Mr. W. Mattieu Williams. The Second Course will be by Dr. W. H. Corfield, M.A., on "Household Sanitary Arrangements;" it will consist of six lectures, to commence on February 17. The Third Course will be by Mr. W. H. Preece, on "Recent Advances in Telegraphy." A course of two lectures will be given by Dr. B. W. Richardson, M.A., LL.D., F.R.S., on "Some Further Researches in Putrefactive Changes," in continuation and completion of his course of Cantor Lectures given last session.

A NEW application of the electric light has just been made by some German River Steamboat Companies. Experiments made on the steamers plying on the Weser and Elbe Rivers having proved perfectly successful these steamers will henceforth be illuminated by electricity.

THE captain of the steamboat *Chillon*, the Geneva correspondent of the *Times* writes, which was caught in the storm on the morning of January 2, describes in a letter to the local papers a scene which is not witnessed once in a generation. On Lake Leman, between Rivaz and St. Gindolph, the two winds the *föhn* and the *bise*, met twisting the water up into a column nearly 40 feet high and 10 yards in circumference. It was a veritable waterspout, and, after retaining its position for several minutes, took the form of a vapoury cloud and melted away. The meeting of the *föhn* and the *bise* is more common on the Lake of Lucerne than that of Geneva; but wherever it happens it is terribly destructive, sweeping down the tallest forest trees and wrecking every craft smaller than a steamer.

A SLIGHT shock of earthquake was felt on Friday last at 3 A.M. at Cologne and Eschweiler. From Buir two shocks are reported—the one at 3.15 and the other at 7.43. The *Neue Freie Presse* announces a considerable shock of earthquake from Unterdranburg, which occurred on the 11th inst., at 10.8 A.M. The Central Observatory at Vienna reports a powerful shock at 10h. 18m. 15s. on the same day observed at Klagenfurt. It

lasted thirteen seconds, and was followed by three slighter shocks. The direction was from south-east to north-west. A report from Eisenkappel gives the same time. The shock observed at Cologne, it will be remarked, occurred on the 10th inst., a day sooner.

INVALIDS will be glad to learn that, amidst the severe weather, a comparatively mild climate exists in a part of their own country. A bouquet arrived from Glengariff on Saturday, the 11th instant, comprising wallflower, primrose, primula, stocks, chrysanthemum, scarlet geranium, arbutus-berries, and a rose-bud, all picked from an exposed garden. In Madeira—but five days' journey—ripe bananas and custard-apples are hanging on the trees. Many of the gayest flowers are in full bloom.

IT is proposed at the next meeting of Russian naturalists to unite all Russian scientific societies into one large association, with zoological, botanical, and physiological sections which would have branches at all the Universities.

THE admirable work by Mr. William H. Edwards on the "Butterflies of North America" has been continued by the publication of the seventh part of the second series, which, like its predecessors, is illustrated by five quarto plates of interesting species, drawn by Miss Mary Peart, of Philadelphia. It is especially interesting from the number of observations made by the author, and his correspondence upon dimorphism and polymorphism of a number of the lepidoptera.

WE cannot help expressing our regret at the almost total destruction of the Birmingham Central Reference Library, with its irreplaceable special collections. We have had frequent occasion to speak of the reports of the Birmingham system of libraries, one of the best anywhere. The building which has suffered disaster was close by the Midland Institute, which fortunately has escaped.

DURING the past summer discoveries of a very interesting series of fossil forests were made by William H. Holmes, of the Hayden (U.S.) Geological Survey. The fact of the occurrence of abundant fossil wood, and in some places of fossil trunks *in situ*, had been noted by former visitors to the Yellowstone Park, but nothing had been learned of the manner in which the forests had been preserved, neither had their great extent been suspected. It is found that an extensive series of forests have been buried in the sedimentary formations of the volcanic tertiary, especially in the region drained by the East Fork of the Yellowstone. From the bottom to the top of the highest cliffs rows of upright trunks may be seen, weathered out and ranged along the ledges like the columns of a temple. Throughout a long period of subsidence a constant alternation of land and sea seems to have been kept up by the irregular deposition of fragmentary volcanic products, so that numberless forests grew and sank, one after another, beneath the sea. Fully 4,000 feet of the tree-bearing strata were formed before the final upward movement began. These same strata now cap some of the highest ranges of the Rocky Mountains, and cover an area of upward of 10,000 square miles. The silicified trunks are in many cases from twenty to thirty feet high, and fairly rival the giant trees of California in dimensions.

IN the *Colonies and India* we find a note respecting the employment of sheep as beasts of burden. In Eastern Turkistan and Thibet, for instance, borax is borne on the backs of sheep over the mountains to Leh, Kangra, and Rampur on the Sutlej. Borax is found at Rudok, in Changthan, of such excellent quality that only 25 per cent. is lost in the process of refining. The Rudok borax is carried on sheep to Rampur, which travel at the rate of two miles a day; but, notwithstanding the superior quality and the demand for it in Europe, the expenses attending its transport seriously hamper the trade, which, but for the sheep, would hardly exist at all.

THE proportions of some principal constituents of sea-water have recently been determined by Herr Jacobsen, from forty-six samples of water taken from the most different regions and at different depths, during the expedition of the *Gazelle*. With regard to carbonate of lime, he obtains an average of 0·269 parts of it in 10,000 parts of sea-water; the minimum was 0·220 parts, and the maximum 0·312 parts. Such differences he attributes mainly to experimental errors, and draws the simple conclusion (not favourable to some interesting biological and geological speculations) that the proportion of carbonate of lime in sea-water varies but slightly. The influence of extensive separation of the carbonate of lime by organisms and that of extensive local replenishing of the water with the carbonate are speedily equalised by ocean currents and obliterated for analysis. One region of the ocean does not afford better life conditions for lime-secreting animals than another (by containing more carbonate of lime), and among the causes from which most of such animals are found on coasts and at comparatively small depths is not to be reckoned that adduced by J. Davy, that in the open sea the carbonate almost wholly disappears. Nor is there ground for Forchhammer's supposition that those animals must be capable of changing the sulphate of lime into the carbonate. The author found but little variations also in the proportions of chlorine and sulphuric acid (the chlorine was somewhat the more constant). The observations in general point to a rapid mixture of the sea-water of different regions by currents both horizontal and vertical.

A RECENT number of *La Nature* gives the following statistics of education in Germany and France:—Of the 86,177 conscripts enrolled in 1877 in the German army 78,622 had received primary instruction in the German tongue, 5,415 in other tongues, and 2,140 or 2·483 per cent. could neither read nor write. The district of Posen furnished the largest contingent of this last category, 11·20 per cent.; then follow Prussia, Silesia, Pomerania, Westphalia, Hanover, Brandenburg, Sleswig-Holstein, the Rhine provinces, Hesse Nassau, and lastly Hohenzollern, of which all the conscripts had received primary instruction. According to the census of 1876 there are, in France, 4,502,894 children of six to thirteen years of age. The number of primary schools is about 71,547, of which 9,352 are absolutely gratuitous. It is reckoned that there are 624,743 children who do not attend any school.

THE new railway bridge across the Lim fjord in the Danish province of Jütland was opened for traffic on December 15.

HERR SCHAPER, an eminent Berlin sculptor, has just finished the model for a bust of the late Prof. Braun, for many years director of the Berlin Botanical Gardens. The bust will be executed in bronze and will be erected in the gardens upon a granite pedestal of 2 metres height.

WE have received parts 1 and 2 of vol. ii. of the *Transactions* of the Watford Natural History Society, containing several papers which show that the Society continues to do good work among the animals and plants of Hertfordshire.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. Wm. Trent; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. Carroll; a Common Marmoset (*Hapale jacchus*) from South-East Brazil, presented by Mrs. Currey; a Triangular Spotted Dove (*Columba guineæ*) from South Africa, presented by Col. F. C. Hassard, C.B.; a Great Eagle Owl (*Bubo maximus*), European, deposited; a Bar-winged Rail (*Rallina pœciloptera*) from the Fiji Islands, purchased.

INDO-OCEANIC RACES

Two papers of considerable interest on the peoples of the Pacific and Indian Islands were read at the last meeting of the Anthropological Institute. The first of these papers, by the Rev. S. J. Whitmee, so long resident in Samoa, was for the purpose of proposing a revised nomenclature of what he calls the Inter-Oceanic races of men. There is much confusion, it is admitted, in the use of geographical and ethnographical names in the Pacific. Polynesia is employed by some for all the intertropical islands eastward of New Guinea. By others it is used for those islands which are east of Fiji, while Melanesia is employed for the southern islands from Fiji westward, and Micronesia for the northern island. Mr. Whitmee proposes that Polynesia should be uniformly employed in the wider signification, and that the different portions be indicated by east, west, and north-west, just as we indicate the parts of a continent.

The term *Inter-Oceanic Races* is used for the people found in Madagascar, Australasia, the Indian Archipelago, Formosa, and Polynesia. In this region there are two classes of people, who may be superficially described as *dark* and *brown*.

The dark people comprise three very distinct races: 1. The Australians, who may bear the name *Australs;* 2. The people found in the Andaman Islands, the interior of the Malacca peninsula, and some portions of the Indian Archipelago, who already have a good name, viz., *Negritos;* 3. The woolly-haired people of Western New Guinea, the Aru, and other islands in the Indian Archipelago, and Western Polynesia. Two names have been used for these—Papuan and Melanesian, and Mr. Whitmee proposes to keep *Papuan* and drop Melanesian. Where these Papuans are somewhat mixed with brown Polynesian blood, they may be conveniently known as sub-Papuan.

The people known as Alfurese in the Indian Archipelago Mr. Whitmee does not regard as a separate people. As used by the Malays, Alfuro appears simply to mean non-Mahommedan and non-Christian—pagan wild men, whether brown or black. Hence Alfuro cannot be used as an ethnic appellation.

The brown people found, from Madagascar, through the Indian Archipelago, in Formosa, in north-west and eastern Polynesia and in New Zealand, Mr. Whitmee regards as having sprung from one stock which had its home in the Indian Archipelago or the Malacca peninsula. For this family he wishes to retain Baron von Humboldt's name, *Malayo-Polynesian;* not because it is the best possible name, but because it is in use and well understood.

There are five branches of this family: 1. Mr. Whitmee believes the first branch which broke off from the parent stock was that which went across the Pacific to Eastern Polynesia and New Zealand. These people probably retain more of the primitive condition of the parent stock than the others, owing to their isolation. But it is almost certain they have to some extent deteriorated from that condition. This race, which does not now possess a satisfactory collective name, he proposes to call *Sawaióri:* this word being compounded from the following representative names, *Sa*-moa, Ha*wai-i*, and Ma-*ori*, following the precedent of the Horsoks of North Thibet, whose name is from *Hor*-pa and *Sok*-pa. 2. A much later migration went westward to Madagascar, and these people bear the appropriate name *Malagasy.* Probably an approximate date of this migration may be fixed by the presence of a few Sanscrit words in the Malagasy language. 3. Mr. Whitmee is unable to express any opinion as to when the *Formosan* migration took place. 4. The latest exodus from the Indian Archipelago was doubtless that which went to north-west Polynesia (Melanesia). For these people he proposes the name *Tárapon*, from Tárawa, in the Gilbert group (used by Mr. Horatio Hall for the language of that archipelago) and Pónape, a representative atoll of the Caroline group. 5. For that branch of the family found still in the Indian Archipelago he proposes to use the generic name *Malayan.* He believes all these people may be included under this term, and that the differences which exist between them may be accounted for by the isolation of some, while others have had a greater mixture of foreign blood, and have been more in contact with external culture and other influences which have changed them since the family has been broken up.

At the eastern end of New Guinea there are mixed people, who may be called *sub-Sawaióri*, or *sub-Malayan*, as their affinities with one or other of these divisions may hereafter prove to be.

The following table shows in compact form the divisions proposed by Mr. Whitmee:—

Inter-Oceanic Races of Men.	Dark Races— ? Negrito-Polynesians	Austral	Australia.
		Negrito	Andaman Is. Samang, &c.
		Papuan	Aru Is. Western New Guinea. Western Polynesia.
	Brown Stock— Malayo-Polynesians	Sawaióri	Samoa. Hawaii. New Zealand, &c., &c.
		Malagasy.	Madagascar.
		Formosan.	Formosa.
		Malayan	Malays of Sumatra, &c. Javanese, &c., &c.
		Tárapon	Caroline Is. Marshall Is. Gilbert Is.

A lively discussion followed, in which Mr. Wallace, Prof. Flower, and Mr. A. H. Keane took part; the two former, while approving of some of Mr. Whitmee's proposed changes, preferred, on the whole, to utilise existing terms. Mr. Keane, in the main, supported Mr. Whitmee's conclusions; indeed, Mr. Whitmee acknowledged his indebtedness to Mr. Keane for several important suggestions contained in his paper.

The second paper, by the Rev. W. G. Lawes, recently returned from a three years' residence at Port Moresby, New Guinea, was an extremely interesting series of ethnological notes on the Motu, Koitapu, and Koiari tribes of New Guinea.

It is extremely important that all statements about New Guinea should be specific as to locality. It is even more important with reference to the people than to the country, the diversities of race and tribe are so numerous. Twenty-five different dialects and languages are spoken, to the writer's knowledge, in the 300 miles of coast extending from Yule Island to China Straits. Port Moresby is the centre of the Motu district, and is in lat. 9° 30′ S. and long. 147° 10′ E. The Motu were fully described by Dr. W. Y. Turner in a paper published in the *Journal* of the Institute, May, 1878. So far as the Motu is concerned Mr. Lawes' paper was simply supplementary.

Great importance is attached among the Motu to the tattooing of the women as a means of enhancing beauty. No importance seems to be attached by them to the pattern. The men are sometimes slightly tattooed, but with them it is a decoration of honour, and shows that the wearer has killed some one.

The taboo system of Polynesia is practised on many occasions and for many purposes.

The spirits of the departed go away to ocean space (their *hades*), and ultimately find their way to the place which is associated in the native mind with plenty and animal enjoyment.

The legend of the Motu respecting the origin of fire is that smoke being seen out to sea, the animals assembled and volunteered to fetch it. The snake, bandicoot, bird, and kangaroo, all started, but came back without it. The dog then went, and succeeded.

The Koitapu are now for the most part to be found living at one end of the Motu villages although preserving their distinctness and separateness. They are also to be found in little groups of a few houses a little way inland, on a hill overlooking the sea all through the Motu district. The typical Koitapu man is slightly darker in colour than the Motu, and the hair is frizzy, not woolly. The principal differences between the Koitapu and Motu are the following:—

Language.—This is essentially different from the Motu and coast tribes. In a vocabulary of 250 words there are only 12 words which have any affinity for coastal or Malayo-Polynesian dialects.

Food and Cooking.—Their bill of fare is more extensive than the Motu, and the mode of cooking different.

Ornaments.—Those different to the Motu are the breastplate and feather head-dress.

Weapons and Manufactures.—The weapons are stone clubs and spears; the bow and arrow is confined to coast tribes. A netted bag and peculiar kind of matting are made by Koitapu, but the knowledge of pottery is confined to coast tribes.

The Koitapu excel in hunting, but the coast tribes are fishermen. The Motu are the conquerors and superior race, but have a superstitious fear of the Koitapu and inland tribes. The

Koitapu are supposed to have power to bewitch and cause disease, also to prevent rain from falling.

The Motu take presents to Koitapu in case of disease, and the women sometimes suck the seat of pain in the same manner as described in Sir J. Lubbock's "Origin of Civilisation," pp. 27, 28. There are many indications that the Koitapu are now but a small remnant of what was once a numerous and powerful race.

The Koiari are closely allied to the Koitapu, and inhabit the mountains at the back of the Motu and Koitapu district. They consist of a number of scattered tribes. They are physically inferior to the Motu and Koitapu, but more numerous. They are small in stature, dark in colour, and dirty in person. Their hands and feet are remarkably small. Their villages are built on the ridge of a hill. Tree houses are common, almost every village having one at a considerable height. Their language is similar to Koitapu. They cultivate the soil carefully, and are great hunters. The women are more degraded than among the Koitapu or Motu, and polygamy is more common.

The dead are laid out for some weeks in the house, and then exposed to sun and smoke until perfectly dry. When the bones fall apart they are collected and tied up in a bundle and hung up in the deserted house or in a tree close by.

The mode of salutation among the Koiari is peculiar. They salute their friends by chucking them under the chin.

They are great chewers of the betel-nut, and are very eager to obtain salt. They barter their produce occasionally with the Motu at Port Moresby for fish, cocoa-nuts, salt, and pottery.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 11, 1878.—In a valuable paper on the passage of the galvanic current through iron, Herr Auerbach describes experiments with reference to the effect of longitudinal magnetisation of iron bars or wires on their resistance, and to the extra currents at closing and opening of the circuit, explained by a transverse or circular magnetisation. Circularly magnetic iron conducts a current worse, the stronger the circular magnetisation. The resistance of longitudinally magnetised iron may be less or greater than that of unmagnetic; in the former case the resistance-function has nowhere a minimum or maximum; the resistance rises steadily from the state of saturated longitudinal, to that of saturated circular, magnetism; and this is realised in hard steel. In the other case the resistance-function has a minimum for the unmagnetic state. Herr Auerbach explains the effects observed on the hypothesis of rotatable molecular magnets, and indicates the bearing of his views on them on the fundamental laws of galvanism, and the galvanic constants of iron.—In a third series of experimental magnetic researches, Herr Fromme deals with two modes of magnetising a rod with a spiral conveying a galvanic current. It may be inserted in the spiral after the circuit has been completed, and withdrawn while the current is still flowing; or it may be inserted before the circuit is closed, and withdrawn after it is opened. He now obtains a distinct difference, unperceived before, between the effects, and the causes of the phenomena are thought to be not of secondary nature (or very little so), but deducible from the essence of magnetism. The results of experiment are found to agree better with the Neumann-Kirchhoff theory, when the latter of the two above methods is abandoned.—Herr Ritter communicates a first paper of researches on the height of the atmosphere, and the constitution of gaseous cosmical substances. On the two hypotheses of an indifferent state of equilibrium in the atmosphere, and of the oxygen and nitrogen retaining approximately, in all changes of condition, the properties of a so-called perfect gas, he arrives theoretically at a height of 40 km. for the atmosphere, whereas Schiaparelli's observations make it more than 200 km. He removes this discrepancy by supposing that, in the rise of the air-masses, not only aqueous vapour, but oxygen and nitrogen, pass into the state of aggregation of a snow-cloud.—Dr. Kolacek studies mathematically the influence of capillary surface-pressure on the velocity of propagation of water-waves.

SOCIETIES AND ACADEMIES

London

Royal Society, January 9.—"Note on the Inequalities of the Diurnal Range of the Declination Magnet as recorded at the Kew Observatory," by Balfour Stewart, F.R.S., Professor of Natural Philosophy in Owens College, Manchester, and William Dodgson.

We are at present engaged in searching for the natural inequalities of the above range, more especially for any of which the period is between 24 and 25 days. We find strong evidence of an inequality of considerable magnitude of which the period is 24·00 days, very nearly. We have also found preliminary evidence of the existence of two considerable inequalities having periods not very far from 24·65 and 24·80 days. These two appear to come together in about 11 years, but we cannot yet give the exact time of this.

We have not found a trace of any inequality with a period of 24·25 days.

"Some Experiments on Metallic Reflexion," by Sir John Conroy, Bart., M.A. Communicated by Prof. G. G. Stokes, Sec. R.S.

He finds that when light is reflected from a polished surface of gold or copper in contact with various media, the angle of principal incidence diminishes, and the principal azimuth increases with the increase of the refractive index of the medium in contact with the metallic surface; and further, the diminution in the value of the principal incidence appears to be nearly in proportion to the increase of the refractive index of the surrounding medium.

He states that the values of these angles for gold with red light are:—

	Principal Incidence.	Principal Azimuth.
	° ′	° ′
In air	76 0	35 27
In water	72 46	36 23
In carbon bisulphide	70 03	36 48

Assuming that the angle of principal incidence for a metal is the same as the angle of polarisation of a transparent substance, that is the angle whose tangent is equal to the refractive index, the value of that angle in air, as deduced from the measurements made in water and carbon bisulphide by multiplying the tangent of the principal incidence in those media by their refractive indices is 76·53 and 77·22 instead of 76.

"Researches on the Absorption of the Ultra-Violet Rays of the Spectrum by Organic Substances," by W. N. Hartley, F.Inst. Chem., F.R.S.E., F.C.S., Demonstrator of Chemistry, King's College, London, and A. K. Huntington, F.Inst. Chem., A.R.Sc. Mines, F.C.S. Communicated by Prof. G. G. Stokes, Sec.R.S.

The following were the conclusions reached:—

1. The normal alcohols of the series $C_nH_{2n+1}OH$ are remarkable for transparency to the ultra-violet rays of the spectrum, pure methylic alcohol being as nearly so as water.

2. The normal fatty acids exhibit a greater absorption of the more refrangible rays of the ultra-violet spectrum than the normal alcohols containing the same number of carbon-atoms.

3. There is an increased absorption of the more refrangible rays corresponding to each increment of CH_2 in the molecule of the alcohols and acids.

4. Like the alcohols and acids, the ethereal salts derived from them are highly transparent to the ultra-violet rays, and do not exhibit absorption-bands.

In order to ascertain whether isomeric bodies exhibited similar or identical absorption-spectra, a series of benzene derivatives was examined. From the great absorptive power of this class of substances it was found necessary to use very dilute solutions, even though the cells holding the liquids were not more than 0·75 inch in thickness. Curves were plotted by taking the proportions of substances in solution as ordinates, and the position of absorption-bands as abscissæ, and these curves are highly characteristic features of very many compounds. About twenty diagrams have thus been made.

The following is a summary of the chief points of interest appertaining to benzene and its derivatives:—

1. Benzene, and the hydrocarbons, the phenols, acids, and amines derived therefrom, are remarkable firstly, for their powerful absorption of the ultra-violet rays; secondly, for the absorption-bands made visible by dissolving them in water or alcohol, and diluting; and thirdly, for the extraordinary intensity of these absorption-bands, that is to say, their power of resisting dilution.

2. Isomeric bodies, containing the benzene nucleus, exhibit widely different spectra, inasmuch as their absorption-bands vary in position and in intensity.

3. The photographic absorption spectra can be employed as a means of identifying organic substances, and as a most delicate test of their purity. The curves obtained by co-ordinating the extent of dilution with the position of the rays of the spectrum absorbed by the solution form a strongly-marked and often a highly characteristic feature of many organic compounds.

There is a curious feature in connection with the position of the absorption bands; at the less refrangible end they either begin at line 12 Cd or line 17 Cd, and those which begin at 12 end a little beyond 17.

No napthalene or anthracene derivatives have yet been examined, and very few substances of unknown constitution—hence most interesting results may be anticipated from a continuation of this research, and this contribution must be accepted rather as a bare commencement of the subject than its conclusion.

Mathematical Society, January 9.—C. W. Merrifield, F.R.S., president, in the chair.—Dr. J. Hopkinson, F.R.S., was admitted a Member.—The following communications were made to the Society: On a theorem in elliptical functions, by Prof. Cayley, F.R.S.—On a new modular equation, by Prof. H. J. S. Smith, F.R.S.—On coefficients of conduction and capacity of two electrified spheres, by Prof. Greenhill.—On certain systems of partial differential equations of the first order with several dependent variables, by Prof. Lloyd-Tanner.

EDINBURGH

Royal Society, December 16, 1878.—Prof. Kelland, president, in the chair.—The first paper was on the action of light on the iris, by Mr. William Ackroyd. In the paper Mr. Ackroyd suggested certain methods for determining whether the amount of light admitted to the eye had an influence on the pupil or not. Certain of the suggested methods had reference to light emanating from a bright point held close to the eye, while another dealt with rays of light emanating from a bright point at a distance.—The next paper was by Mr. John Aitken, on a new variety of ocular spectrum.—Mr. Alex. Macfarlane, D.Sc., M.A., then read the first half of a paper on the principles of the logical algebra. In it he entered into a minute examination of the principles of the logical calculus, as laid down by Prof. Boole in his treatise on the "Laws of Thought," and advanced a new theory of the operation of the mind, founded upon the analysis of language and the nature of mathematical reasoning.

MANCHESTER

Literary and Philosophical Society, December 10, 1878.—J. P. Joule, D.C.L., LL.D., F.R.S., president, in the chair. On the combinations of aurin with mineral acids, by R. S. Dale, B.A., and C. Schorlemmer, F.R.S.—On the estimation of small excesses of weight by the balance from the time of vibration and the angular deflection of the beam, by J. H. Poynting, B.A., B.Sc.

PARIS

Academy of Sciences, January 6.—M. Fizeau in the chair.—M. Edm. Becquerel was elected Vice-President for 1879.—M. Fizeau gave information regarding the publications of the Academy, and the changes among members and correspondents during the year. The deceased members are Becquerel, Regnault, Delafosse, Bernard, Belgrand, and Bienaymé. Deceased correspondents, Didion, Secchi, Mayer, Malaguti, Leymerie, De Vibraye, De Valdrôme, Shumann, Rokitanski, and Lebert.—The following papers were read:—Reply to M. Pasteur, by M. Berthelot.—On a gigantic isopod from a great depth in the sea, by M. Milne-Edwards. This creature, called *Bathynomus giganteus*, was brought up from a depth of 955 fathoms, on the north-east of the bank of Yucatan, by the American expedition in the *Blake*, which started in December, 1877, under A. Agassiz. It measures 0·23m. in length and 0·10m. in breadth, and is specially distinguished by its respiratory apparatus. This has the form of plumes or tufts from branching stems under the false abdominal feet, which serve as a kind of opercular system. The whole system, including a hollow part in the false abdominal feet, may be injected with coloured liquid. Doubtless the arrangement is specially adapted for the great depth at which the animal respires. The eyes are very well-developed (which would hardly have been expected in a very dark medium). They are each formed of nearly 4,000 square facettes, and, instead of being above the head, as in all errant Cymothoadians, they are lodged under the frontal border, at each side of the base of the antennæ. M. Milne-Edwards places the animal in a new family, which he designates *Branchiferous Cymothoadians*.—On the parallelism of axes of rotation, by M. Sire. The tendency to this is illustrated by a simple apparatus.—On an economical method of bathing adopted in the 69th Regiment of Infantry, by Dr. Haro. Each man takes his place in a tub of warm water, and receives a pulverulent douche of warm water, at the same time rubbing himself with black soap and a brush; then comes a second douche of warm water, then washing with cold water. 80 to 100 men are thus washed daily at a cost of 1 fr. 20 per *séance*, or 0·012 fr. per man.—On the existence of the intra-Mercurial planet indicated by Leverrier, by M. von Oppolzer. He finds (by calculation) the existence of such a planet very probable, but thinks it cannot be identical with any of the two objects observed by Mr. Watson.—Double nebulæ in motion, by M. Flammarion. He suggests that such may be the origin of systems of double stars. Having compared the observations made on 5,000 catalogued nebulæ, he indicates those which show a certain motion, and the nature of it.—On the formation of organic ultramarines, by M. de Forcrand. He obtains such products by heating ultramarine of silver with chlorides or iodides of different alcoholic radicles.—On the separation of ethylamines, by MM. Duvillier and Buisine.—On a new group of silicified stems of the coal epoch, by M. Renault. Completing, in some sort, the observations of Prof. Williamson, he finds among the fossils of Autun a series of types parallel (as regards the growth of the ligneous axis) to the Sigillarineæ, but related, on the other hand, to stems of Cordaites by certain details of structure. This new group he designates *Poroxyleæ*, from the nature of their wood; they present the three types of stem found in Sigillarineæ.—On the disease of the chestnuts, by M. De Seynes. The parasite mycelium forms a superficial and a deep network, which destroy the cellular layers of the root, the richest in protoplasm; the liberian and ligneous fibres are not attacked.—On dental grafting, by M. David. He distinguishes the graft by *restitution* and the graft by *borrowing*. The former consists in reimplantation after extraction, and is resorted to to rectify direction, to treat caries and periostitis easily, or to facilitate operations on some other tooth in the mouth. In twenty-two cases, only one proved unsuccessful. The graft by borrowing consists in substituting a sound tooth (which has had to be extracted from the same or another mouth), for a bad one. Or a sound root from a lower animal may be inserted for a bad one, as base for a pivoted artificial tooth.—On animal grafting in its applications to the therapeutics of certain lesions of the dental apparatus, by M. Magitot. He furnishes some data regarding graft by restitution in the case of chronic periostitis of the top of the root of teeth, &c. His success amounts to about 92 per cent. (sixty-two operations, fifty-seven cures).—M. Delesse was elected member in mineralogy, in room of the late M. Delafosse.

GAS VERSUS ELECTRICITY

THE gas companies are at last awakening to the peculiarity of their position, and gas-shareholders are recovering their confidence in the stability of their property. It is interesting to observe how steadily the shares in all the great gas companies have during the last few weeks been rising, and unless any untoward event occurs there is no reason why in a short time they should not recover the position they so singularly lost in August of last year. Looking dispassionately upon the events that have occurred, it is difficult to understand how such a panic and scare could have arisen. Nothing of any sort or kind has been discovered either in the laws of electricity or in their application to electric lighting to account for it. We know no more of the electric light now than we did in 1862, when as great a display was made in our Exhibition of that year as was made in the French Exhibition of last year. There is no doubt, however, that the enterprise of our neighbours on the other side of the Channel in lighting up so brilliantly one of their grand new streets produced a sensation that will not easily be forgotten. Englishmen never like to be beaten. We are accustomed to be startled by inventions from the other side of the Atlantic, but we are not accustomed to be beaten either in commercial enterprise or in inventive skill by our neighbours on this side of the Atlantic. Hence, all of those, whose name is legion, who visited Paris last year came back with exaggerated ideas of the effect of the electric light in the Avenue de l'Opéra, and spread through England a profound opinion of the value of electricity as a means of illumination.

It seems to be forgotten that only three years ago a competitive trial of gas and electricity was made in the clock tower of the Houses of Parliament. Each of these lights were tried for several months, the electric light being a Serrin lamp lit by a Gramme machine; and that, after a very careful examination, gas was successful, was adopted, and is now used by the Office of Works.

Again, it seems to be forgotten that the Elder Brethren of the Trinity House have been experimenting upon this question ever since 1857, and that the results of their experiments have only led to the adoption of the electric light in three of their lighthouses. If the electric light had had the wonderful advantage over gas or oil that its projectors profess for it, surely the governors of such an institution as the Trinity House would have fitted up all the lighthouses upon our coasts with this wonderful light.

The recent experiments, however, have shown both the strength and weakness of the position of the gas companies. Their strength consists in their being in possession of the ground; their weakness consists in their producing only a poor light—and a very poor light—when compared with electricity. But is there any reason why this weakness should continue? Is there any reason why gas should remain such an indifferent light? There is none but that of expense, and expense will not deter people from having a better light if they can only get it. The Phœnix Company has taken the question in hand, and has shown in the Waterloo Road what can be done with gas when the question of expense is not considered. Indeed, it would almost seem, from the experiments that have been made, that the quantity of light to be produced by gas is only a question of the quantity of gas consumed in a given space. There are now burning in the Waterloo Road two brilliant gas lamps, giving a light of 500 candles, and this is greater, in point of fact, than the intensity of the light developed by any one of the electric lights that are now on trial in the thoroughfares of London. There is, however, a defect in gas light which remains to be eradicated, and that is the colour of the light. The one great advantage which the electric light has over gas is that the electric light, owing to its very high temperature, produces rays of every degree of refrangibility, and therefore, as an illuminating power it is equal to that of the sun. But gas light, owing to the lowness of its temperature, is deficient in blue rays, and is therefore not so effective in discriminating colours as the electric light.

A very marked advance towards perfection in this direction in gas lighting has been made in the albo-carbon process, by which the gas burnt is enriched with the vapour of naphthaline—a refuse of gas manufacture. This process is being introduced by Mr. Livesey, and, to judge by the experiments that have been shown, it is very promising indeed. The intensity of the light of a gas burner is improved at least five times, and in some experiments witnessed by the writer the improvement was as much as twenty times.

The tentative trials that are being made with the electric light in London cannot be said to be very successful. That at Billingsgate was certainly a fiasco, that on the Embankment is very brilliant, but we have yet to learn its cost, and there is no doubt whatever that the efficiency of the light is very much less than that usually ascribed to the electric light. The trial on the Holborn Viaduct is not a success. The experiment seems to be conducted by some one who is not experienced in the working of electric circuits, for occasionally all the lamps are found extinguished, on other occasions only a portion of them are burning, and frequently they are very dull. It is quite difficult even at the distance of the Post Office to distinguish the gas from the electric lamp. The same effect is observed on crossing Blackfriars Bridge and looking towards the Houses of Parliament when there is the slightest mist in the air, and it is quite evident that the electric light has no more—if as much—penetrative power than gas.

A most complete and careful inquiry into the working of the electric light has been made by Mr. Louis Schwendler for the East Indian Railway Company, and his results are extremely interesting. He has recommended the introduction of the light into certain railway stations where no gas exists, and the system he proposes to use is the Siemens dynamo-machine and one Serrin lamp, and thereby save that waste which the multiplication of the light unquestionably produces. He proposes to distribute this single light by diffusion on a plan originally suggested by the Duke of Sutherland. His investigation has been conducted in a thoroughly scientific spirit, and when his report is published it will be a very valuable addition to our knowledge of the theory of the electric light. It has

been shown by the writer that the full effect of the current can only be obtained by one lamp on a short circuit, and that when adding to the lamps by inserting more of them on the same circuit, or on a circuit so that the current is subdivided, the light emitted by each lamp is diminished in the one case by the square, and in the other case by the cube of the number of lamps so inserted. Dr. Siemens maintains also the concentration of the power on one light, but other experimenters are endeavouring to partially multiply the light. For instance, M. Rapieff, in the *Times* office, very successfully distributes six lights about the office, and Ladd and Co., with the Wallace form of machine, also distribute six lights over the Liverpool Street Station. Although there is undoubtedly a loss of power in this distribution of the lamps, there may be an advantage in such distribution in cases like printing offices and railway stations. A successful experiment has been made by the British Electric Company in lighting up some of the stations of the Metropolitan Railway Company, and the India Rubber and Gutta Percha Company have been successful in lighting up the London Bridge station of the London Brighton and South Coast Railway Company. In all these cases we have scarcely emerged from the sphere of experiment. The electric light has not yet been permanently introduced on any large scale. Many are trying it, many are captivated by the brilliancy of the light, and many in their eagerness to keep up with the spirit of the age, are introducing it, as, for instance, the London Stereoscopic Company, and the Messrs. Nichols, the clothiers in Regent Street, where, however, the light does not appear to give very great satisfaction through its fluctuation.

We were led to expect very much from the experiments of Mr. Werdermann, but his attempt to subdivide the light seems to have subsided, for we have heard nothing of it for some time past. Again, we have heard no more of M. Arnaud's discovery, and the accounts that reach us from America of the doings of the Sawyer-Mann light, and of the supposed discoveries of Mr. Edison, are unworthy of attention.

The present state of the electric light question may therefore be said to be a tentative one, and the gas companies are with much enterprise now giving their retort courteous by showing that they are in a position—if people choose to pay for it—to give quite as powerful a light as the electric light; and, let us hope, before long that it will be quite as perfect. There can be no doubt that the use of electricity for the production of light is a very wasteful as well as a costly process, for the energy that is generated in the machine is not all consumed in the lamp, but is proportionately distributed over the whole circuit. It is therefore not utilised only in the place where it is wanted, as in the case of gas. If we are using a certain amount of energy in an electric lamp to light a street, we are wasting as much if not more energy in the street in maintaining the current to produce that light.

There are three points which all electric lights for general purposes should be required to attain. The first is a brilliancy far exceeding that of any known lamp; the second is a durability greater than that which would be required for night operations in England; and the third is absolute steadiness, to enable work to be conducted without affecting the eyes. There is no electric light that has yet been introduced which supplies us with these desiderata.
